This book contains information obtained from authentic and highly regarded sources. While all reasonable efforts have been made to publish reliable data and information, neither the author[s] nor the publisher can accept any legal responsibility or liability for any errors or omissions that may be made. The publishers wish to make clear that any views or opinions expressed in this book by individual editors, authors or contributors are personal to them and do not necessarily reflect the views/opinions of the publishers. The information or guidance contained in this book is intended for use by medical, scientific or health-care professionals and is provided strictly as a supplement to the medical or other professional's own judgement, their knowledge of the patient's medical history, relevant manufacturer's instructions and the appropriate best practice guidelines. Because of the rapid advances in medical science, any information or advice on dosages, procedures or diagnoses should be independently verified. The reader is strongly urged to consult the relevant national drug formulary and the drug companies' and device or material manufacturers' printed instructions, and their websites, before administering or utilizing any of the drugs, devices or materials mentioned in this book. This book does not indicate whether a particular treatment is appropriate or suitable for a particular individual. Ultimately it is the sole responsibility of the medical professional to make his or her own professional judgements, so as to advise and treat patients appropriately. The authors and publishers have also attempted to trace the copyright holders of all material reproduced in this publication and apologize to copyright holders if permission to publish in this form has not been obtained. If any copyright material has not been acknowledged please write and let us know so we may rectify in any future reprint.

Except as permitted under U.S. Copyright Law, no part of this book may be reprinted, reproduced, transmitted, or utilized in any form by any electronic, mechanical, or other means, now known or hereafter invented, including photocopying, microfilming, and recording, or in any information storage or retrieval system, without written permission from the publishers.

Contents

Preface
Editors
Contributors

VOLUME ONE

SECTION I: BACKGROUND ISSUES

1 History of Urogynecology and Female Urology
Jane A. Schulz, Harold P. Drutz, and Jack R. Robertson

2 Epidemiology: United States
Ananias C. Diokno, Scott E. Kalinowski, and Benjamin J. Girdler

3 Epidemiology: South America
Paulo C.R. Palma, Miriam Dambros, Fábio Lorenzetti, and Fabio Thadeu Ferreira

4 Epidemiology: Europe
Ian Milsom and Maria Gyhagen

5 Epidemiology: Australia
Christopher Benness

6 Epidemiology: Asia
S.S. Vasan and Reena Mallesh

7 Epidemiology of Female Pelvic Floor Dysfunction in Africa
Stephen Jeffery and Peter de Jong

8 Tackling the Stigma of Incontinence
Diane K. Newman

9 Natural History and Prevention of Urinary Incontinence and Urogenital Prolapse
C.K. Madhu, R. Trochez, and Robert M. Freeman

10 Medical Error and Patient Safety in Surgery
Roxane Gardner

SECTION II: ROLE OF PATIENT REPORTED OUTCOME MEASURES AND HEALTH ECONOMICS

11 Section Introduction: The Role of Patient-Reported Outcome Measures and Health Economics
Cornelius J. Kelleher

12 **Patient-Reported Outcomes: From Development to Utilization**
Karin Coyne and Chris Sexton

13 **Patient-Reported Outcome Questionnaires to Assess Health-Related Quality of Life and Symptom Impact**
Cornelius J. Kelleher, Ramandeep Basra, and Alexandra E. Ridout

14 **Patient-Reported Outcome Questionnaires to Screen and Measure Satisfaction, Expectations, and Goal Achievement**
Zoe S. Kopp and Christopher J. Evans

15 **Questionnaires to Assess Sexual Function**
Claudine Domoney and Tara Symonds

16 **Questionnaires to Assess Bowel Function**
Said Mohamed, David Chatoor, and Andrew Williams

17 **International Consultation on Incontinence Modular Questionnaire**
Nikki Cotterill and Paul Abrams

18 **Electronic Personal Assessment Questionnaire Pelvic Floor**
Stephen Radley and Deepa Gopinath

19 **Questionnaires to Assess Pelvic Organ Prolapse**
Alex Digesu

20 **Economic Aspects of Urinary Incontinence**
Kate H. Moore

SECTION III: STRUCTURE AND FUNCTION OF THE LOWER URINARY AND ANORECTAL TRACTS IN WOMEN

21 **Anatomy**
John O.L. DeLancey

22 **Embryology of the Female Urogenital System and Clinical Applications**
Dana Weiss and Stephen A. Zderic

23 **Physiology of Micturition**
Shachi Tyagi, Pradeep Tyagi, Naoki Yoshimura, and Michael B. Chancellor

24 **Pharmacology of the Bladder**
Karl-Erik Andersson

25 **Uropathogens and the Lower Urinary Tract**
Leslie Rickey

26 **Classification of Lower Urinary Tract Dysfunction in the Female Patient**
David Staskin and Alan J. Wein

27 **Tissue Engineering and Regenerative Medicine for the Female Genitourinary System**
Manish Patel and Anthony Atala

SECTION IV: DIAGNOSTIC EVALUATION OF INCONTINENCE AND UROGENITAL PROLAPSE

28 History and Examination
Vik Khullar and Rhiannon Bray

29 Bladder Diary and Symptom Scores
Alan Uren and Nikki Cotterill

30 Pad Tests
Marie-Andrée Harvey

31 Basic Urodynamic Tests: Uroflowmetry
Matthias Oelke

32 Basic Urodynamic Tests: Filling and Voiding Cystometry
Hashim Hashim and Paul Abrams

33 Tests of Urethral Function
Kristi L. Hebert, Barry G. Hallner, Ryan M. Krlin, and J. Christian Winters

34 Special Urodynamic Tests: Videourodynamics
Ilias Giarenis and Marcus J. Drake

35 Special Urodynamic Test: Ambulatory Urodynamics
Kevin L.J. Rademakers and Gommert A. van Koeveringe

36 Basic Neurological Evaluation and Referral
David B. Vodušek and Jalesh N. Panicker

37 Imaging of the Upper and Lower Urinary Tract: Radiology and Ultrasound
Andrea Tubaro, Kirsten Kluivers, Federica Puccini, and Antonio Carbone

38 Magnetic Resonance Imaging in Urogynecology
Elisabetta Costantini and Marcus J. Drake

39 Endoscopy
Musaab Sarmad Yassin, John Michael Henderson, and Francis Xavier Keeley

40 Urinalysis
F.M.E. Wagenlehner and Ganesh Thiagamoorthy

SECTION V: CONSERVATIVE AND MINIMALLY INVASIVE THERAPIES

41 The Role of the Continence Nurse
Angie Rantell

42 Behavioral Therapies and Management of Urinary Incontinence in Women
Kathryn L. Burgio

43 Physiotherapy for Urinary Incontinence
Bary Berghmans

44 Pessaries and Devices: Nonsurgical Treatment of Pelvic Organ Prolapse and Stress Urinary Incontinence
Catherine S. Bradley

45 Catheters, Pads, and Pants
Lynette E. Franklin

46 Drug Treatment of Lower Urinary Tract Dysfunction in Women
Ariana L. Smith and Alan J. Wein

47 Peripheral Neuromodulation
John Heesakkers and Jetske van Breda

48 Sacral Neuromodulation in the Treatment of Female Overactive Bladder Syndrome and Nonobstructive Urinary Retention
J.L.H. Ruud Bosch

49 Injectable Bulking Agents in the Treatment of Female Stress Urinary Incontinence
Brian J. Linder, Philip Wanzek, and Deborah J. Lightner

50 Use of Botulinum Toxins in the Management of Female Voiding Dysfunction
David Ginsberg and Ellen Goldmark

VOLUME TWO

SECTION VI: ASSOCIATED DISORDERS

51 The Overactive Bladder
Marcus J. Drake

52 Neurological Disorders
Ricardo R. Gonzalez, Edward J. Sanchez, David Goldfarb, Renuka Tyagi, and Alexis E. Te

53 Nonneurogenic Voiding Dysfunction and Urinary Retention
Bernard T. Haylen

54 Pathophysiological Mechanisms of Chronic Pelvic Pain
Ursula Wesselmann

55 Bladder Pain Syndrome/Interstitial Cystitis
Amina Douglas, Matthew Parsons, and Philip Toozs-Hobson

56 Bacterial Cystitis in Urogynecology: An Update
Nèvine I.D. te West and Kate H. Moore

57 Vaginitis
J.D. Sobel

58 Pregnancy and Childbirth and the Effect on the Pelvic Floor
Philip Toozs-Hobson, Aneta Obloza, and Sara Webb

59 Problems Associated with Sexual Activity

Swati Jha

60 Menopause
Timothy C. Hillard

61 Sports and Fitness Activities
Kari Bø

62 Anal Incontinence
Tony Mak and Simon Radley

63 Constipation
Kaori Futaba, Yvette Perston, Tony Mak, and Simon Radley

64 Female Sexual Dysfunction
Seth D. Cohen and Irwin Goldstein

65 Multidisciplinary Team
Kaori Futaba, Simon Radley, and Matthew Parsons

66 Multidisciplinary Clinic: Urology and Urogynecology
Pallavi Latthe

67 Multidisciplinary Clinics: Specific Considerations for Elderly Care
Claire Sutton and Philip Toozs-Hobson

SECTION VII: SURGERY FOR URINARY INCONTINENCE

68 How and Why Incontinence Surgery Works
Mauricio Plata, Nicolas Fernandez, David James Osborn, and Roger R. Dmochowski

69 Peri- and Postoperative Care
Sushma Srikrishna and Linda Cardozo

70 Traditional Surgery and Other Historical Procedures for Stress Incontinence
Malcolm Lucas, Elizabeth Timbrook Brown, and Roger R. Dmochowski

71 Retropubic Urethropexy
Dudley Robinson and Linda Cardozo

72 Fascial Slings
Aaron Brothers, David James Osborn, Melissa R. Kaufman, W. Stuart Reynolds, and Roger R. Dmochowski

73 Tension-Free Vaginal Tape Procedure For Treatment of Female Urinary Stress Incontinence
Carl Gustaf Nilsson

74 Transobturator Tape for Surgical Treatment of Stress Urinary Incontinence: Outside-In Technique
Emmanuel Delorme and Jean-François Hermieu

75 Single-Incision Minislings
Mickey Karram and Radhika Sharma

76 Readjustable Slings: Safyre and Remeex
Paulo C.R. Palma and Cassio Riccetto

77 Nonsurgical Transurethral Radio Frequency Collagen Denaturation of the Bladder Neck and Proximal Urethra for the Treatment of Stress Urinary Incontinence
Saad Juma, Elizabeth Timbrook Brown, and Roger R. Dmochowski

78 Artificial Urinary Sphincter for Treatment of Stress Urinary Incontinence in Women
David Castro-Diaz, David Staskin, and Roger R. Dmochowski

79 Diagnosis and Treatment of Obstruction Following Incontinence Surgery: Urethrolysis and Other Techniques
Stephen Mock, Melissa R. Kaufman,
W. Stuart Reynolds, and Roger R. Dmochowski

80 Complications of Stress Urinary Incontinence Surgery
Véronique Phé and Emmanuel Chartier-Kastler

SECTION VIII: SURGERY FOR UROGENITAL PROLAPSE

81 Classification and Epidemiology of Pelvic Organ Prolapse
Steven E. Swift

82 Anterior Vaginal Wall Prolapse
Mark D. Walters and Matthew D. Barber

83 Enterocele
Kaven Baessler

84 Rectocele: Anatomic and Functional Repair
Audra J. Hill and Marie Fidela R. Paraiso

85 Vaginal Approach to Fixation of Vaginal Apex
May Alarab, Salomon Zebede, and Harold P. Drutz

86 Open Abdominal Approach to Supporting the Vaginal Apex
Kristina Cvach and Peter Dwyer

87 Laparoscopic and Robotic Approaches to Apical and Vaginal Vault Suspension
Vaneesha Vallabh-Patel and Patrick J. Culligan

88 Uterine Prolapse
Miriam Seitz and Roger P. Goldberg

89 Biological Grafts in Reconstructive Pelvic Surgery
Alexis M. Tran and Peter K. Sand

90 Synthetic Grafts in Pelvic Surgery
William Barone and Pamela Moalli

91 Complications of Synthetic Mesh Used to Repair Pelvic Organ Prolapse
Mickey Karram and John B. Gebhart

92 **Episiotomy and Perineal Repair**
Ranee Thakar and Christine Kettle

93 **Primary Repair of Obstetric Anal Sphincter Injuries**
Abdul H. Sultan

94 **Surgery for Fecal Incontinence**
Julie Ann M. Van Koughnett and Steven D. Wexner

95 **Rectal Prolapse and Other Causes of Fecal Obstruction**
Susanne D. Otto, Kaven Baessler, and Jörn Gröne

SECTION IX: LAPAROSCOPY AND ROBOTICS

96 **Section Introduction: The Role of Laparoscopic Surgery in Urogynecology**
Anthony R.B. Smith

97 **Pelvic Anatomy through the Laparoscope**
Fiona Reid

98 **Training and Accreditation in Laparoscopic and Robotic Pelvic Floor Surgery**
Karl Jallad, Marie Fidela R. Paraiso, and Alfred Cutner

99 **Laparoscopic Colposuspension and Paravaginal Repair**
Arvind Vashisht and Alfred Cutner

100 **Laparoscopic Sacrocolpopexy**
Marcus P. Carey

101 **Laparoscopic Sacrohysteropexy**
Helen Jefferis, Natalia Price, and Simon Jackson

102 **Prevention, Recognition, and Treatment of Complications in Laparoscopic Pelvic Floor Surgery**
Christopher Maher and Nir Haya

103 **The Role of Robotic Surgery**
Orfhlaith E. O'Sullivan and Barry A. O'Reilly

104 **Vesicoscopy**
Philippe Grange and Chrysanthos Kouriefs

105 **Cost-Effectiveness in Laparoscopic and Robotic Surgery in Urogynecology**
Karen Ward

SECTION X: COMPLEX PROBLEMS

106 **Diagnosis of Urogenital Fistula**
Ekene A. Enemchukwu and Benjamin M. Brucker

107 **Transvaginal Repair of Urogenital Fistula**
Barry G. Hallner, Kristi L. Hebert, and J. Christian Winters

108 Transabdominal Vesicovaginal and Vesicouterine Fistula Repair
Howard Goldman and Christopher Tenggardjaja

109 Management of Obstetric Urogenital Fistula
Andrew Browning

110 Urethral Diverticulum and Fistula
Kathleen C. Kobashi

111 Diagnosis and Management of Female Urethral Stricture Disease
Victor W. Nitti and Aqsa Khan

112 Ureteral and Bladder Reconstruction
Nadir I. Osman, Altaf Mangera, and Christopher R. Chapple

113 Gynecological Developmental Abnormalities
Melissa C. Davies and Sarah M. Creighton

114 Pediatric Urogynecology
Angela M. Arlen, Howard M. Snyder, and Andrew J. Kirsch

115 Female Genital Cosmetic Surgery: From Female Genital Cutting to Vaginal Rejuvenation
Lauri J. Romanzi

116 Cosmetic Vaginal Surgery
Robert D. Moore and John R. Miklos

117 Urological Complications of Gynecological Surgery
Monica L. Richardson and Craig V. Comiter

APPENDIX A: Standardization of Terminology
Dirk De Ridder and Marcus J. Drake

APPENDIX B: The Standardization of Terminology of Lower Urinary Tract Function: Report from the Standardization Subcommittee of the International Continence Society
Paul Abrams, Linda Cardozo, Magnus Fall, Derek Griffiths, Peter F.W.M. Rosier, Ulf Ulmsten, Philip van Kerrebroeck, Arne Victor, and Alan J. Wein

APPENDIX C: International Urogynecological Association/International Continence Society Joint Report on the Terminology for Female Pelvic Floor Dysfunction
Bernard T. Haylen, Dirk De Ridder, Robert M. Freeman, Steven E. Swift, Bary Berghmans, Joseph Lee, Ash Monga, Eckhard Petri, Diaa E.E. Rizk, Peter K. Sand, and Gabriel N. Schaer

APPENDIX D: Commentary on the 2009 IUGA/ICS Joint Report on the Terminology for Female Pelvic Floor Dysfunction
Rufus Cartwright

APPENDIX E: Standardization of Terminology of Female Pelvic Organ Prolapse and Pelvic Floor Dysfunction
Richard C. Bump, Anders Mattiasson, Kari Bø, Linda P. Brubaker, John O.L. DeLancey, Peter Klarskov, Bob L. Shull, and Anthony R.B. Smith

APPENDIX F: Good Urodynamic Practices: Uroflowmetry, Filling Cystometry, and Pressure–Flow Studies

Werner Schaefer, Paul Abrams, Limin Liao, Anders Mattiasson, Francesco Pesce, Anders Spangberg, Arthur M. Sterling, Norman R. Zinner, and Philip van Kerrebroeck

APPENDIX G: Developing Evidence-Based Standards for Diagnosis and Management of Lower Urinary Tract or Pelvic Floor Dysfunction

Peter F.W.M. Rosier, Dirk De Ridder, Jane Meijlink, Ralph Webb, Kristene Whitmore, and Marcus J. Drake

APPENDIX H: Standardization of Dynamic Magnetic Resonance Imaging Measurements of Pelvic Organ Prolapse: Can the PICS Line Help?

Diaa E.E. Rizk and Ralf Tunn

Index

Preface

The success of the first three editions of the *Textbook of Female Urology and Urogynecology* and our desire to regularly update and provide a timely and relevant reference textbook in this rapidly evolving field stimulated us to produce this fourth edition. We hope we have again fulfilled our mission by presenting a book that serves as a foundation for established ideas, a review of the current state of the art, and a platform for introducing the dynamic concepts of the future.

We are both proud and humbled to present this fourth edition and take this opportunity to thank all those who contributed their time and effort—thanks also for choosing this textbook for your practices and your libraries. We are particularly grateful to our section editors and appreciate their commitment to producing an authoritative and comprehensive reference book that has demonstrated broad appeal to the wide range of health providers involved in the management of female pelvic floor problems.

We specifically selected these section editors and authors to present an international approach to the numerous female urogenital health issues in order to produce a good balance of knowledge, expertise, and writing skills without the polarization of ideas that can occur as a natural product of geography, training, and interests. Once again, we have included authors with international reputations and others who are newcomers to the field. We recognize that there is a significant overlap between female urology and urogynecology. However, there are also differences, and we hope that these are reflected by having a balance between the healthcare professionals who have written the individual chapters. In the future, readers will continue to evaluate the physicality of a traditional textbook versus a digitized edition, or a website that allows collaborative editing of its content and structure by its users, and this will influence our future as consumers of information and the choice of medium for future editors, authors, and readers.

We are indebted to the publisher, who facilitated production of all four editions. In addition, to quote from the preface of the third edition, “we are most grateful to our patients who place their trust in all of us every day and we hope that this textbook will contribute to their quality of care and to those who will treat them in the future.”

Section I

Background Issues

1 History of Urogynecology and Female Urology

Jane A. Schulz, Harold P. Drutz, and Jack R. Robertson

INTRODUCTION

Having moved into the new millennium, accompanied by many new advances in the field of urogynecology and reconstructive pelvic surgery, it is appropriate to take time to reflect on the events of the last century and to make suggestions for future directions. With the significant increase in our postmenopausal female population, there is a growing demand for improved quality of life and management of pelvic floor dysfunction. No longer do we contemplate *whether* women will grow older but, rather, *how* they will grow older. The life expectancy for women has almost doubled through the twentieth century. In 1923, Professor Sir Arthur Keith, in his Hunterian lecture on “Man’s Posture: Its Evolution and Disorders” [1], stated:

> Every movement of the arms, cough or strain sets going a multitude of “water hammers” within the abdominal and pelvic cavities. Every impulse sets the bladder knocking at the vaginal exit … it is the continual repetition of small forces, more frequently than the sudden application of a great effort which wear down the vaginal defense.

Although it has long been recognized that factors such as childbearing and chronic increases in intra-abdominal pressure contributed to pelvic floor prolapse, only recently has there been growing demand to manage all of the resulting problems. Urinary incontinence is now the most common reason for admission to long-term institutionalized centers in Canada and the United States. Billions of dollars are spent every year on nappy (diaper) and pad products, but this does nothing to correct the underlying problem of incontinence.

Since the inception of medical writing, gynecological and urological conditions have been reported. The Kahun papyrus, circa 2000 BC, described diseases of women including diseases of the urinary bladder. The Ebers papyrus, 1550 BC, classified diseases by systems and organs. Section VI includes a prescription for the cure of a woman suffering from disease of her urine, as well as her womb. Urinary fistula is an example of the intimate relationship of the urinary and genital systems in women. Henhenit lived in the court of Mentuhotep II, about 2050 BC. Her mummy, found in 1935, revealed by radiography an extensive urinary fistula [2].

Reviewing the last century of progress in the new subspecialty of urogynecology and reconstructive pelvic surgery proved to be a tremendous, and somewhat daunting, task. Perhaps the quotation that best summarizes the events that have occurred is the opening sentence from Charles Dickens’ *A Tale of Two Cities*: “It was the best of times, it was the worst of times.” Undoubtedly, we have made tremendous progress in this burgeoning new field; however, a political battlefield was perpetuated with the division of the female pelvic floor between urologists, urogynecologists, gynecologists, and colorectal surgeons. This political feud is cleverly illustrated in the article of Louis Wall and John DeLancey with its well-known drawing of the competing urologist, gynecologist, and colorectal surgeon [3]. This is one of the many challenges that must be overcome in providing overall women’s healthcare as we move further into the twenty-first century. A multidisciplinary approach to managing female pelvic floor dysfunction must be advocated to provide women with appropriate care in the areas of urinary and fecal incontinence, urogenital aging, conservative management, and reconstructive pelvic surgery [4].

Voltaire, the French philosopher of the “Age of Enlightenment” said, “these truths are not for all men nor for all times.” From this, we must humbly accept the concept that the truths we believe in today regarding our management of women with pelvic floor disorders must be constantly reassessed and modified with scientific advancements and research. Similarly, the epigram by Alphonse Karr (1849) “plus ça change plus c’est la même chose” (the more things change, the more they stay the same) also reflects the changes during the past century especially in the field of surgical intervention, where in many cases we have continued to reinvent the wheel. Now, we will review the significant events in this field over the last century.

HISTORY OF THE INTERNATIONAL UROGYNECOLOGY ASSOCIATION

At the Federation International of Gynecology and Obstetrics (FIGO) meeting in Mexico City in 1976, two medical friends, Professor Axel Ingelman-Sundberg, of Stockholm Sweden, and Jack Rodney Robertson, of California, USA, met. It was time to form a new society. The objective was to further the urinary health of females. Both physicians were deeply involved in this work.

Axel Ingelman-Sundberg, renowned for his research, his pioneering in gynecologic surgery, and his teaching at the Karolinska Institute in Stockholm, Sweden, was the catalyst. Sweden had been a founding member of FIGO. Axel tried to persuade FIGO to make International Urinary Incontinence a subcommittee, but they declined. In his capacity as vice president of FIGO, Axel reserved a special room for the formation of the International Urogynecological Association (IUGA). He was elected the first president, to serve 5 years, 1976–1980, by the colleagues who registered as members. They were Abbo Hassan Abbo, MD, Sudan; Wolfgang Fisher, MD, East Germany; Bozo Kralj, MD, Yugoslavia; Oscar Contreras Ortiz, MD, Argentina; Donald R. Ostergard, MD, USA; Eckard Petrie, MD, West Germany; Jack R. Robertson, MD, USA; Mr. Stuart Stanton, MD, U.K.; Ulf Ulmsten, MD, Sweden; and David W. Waller, MD, UK. Ulf Ulmsten, then professor of obstetrics and gynecology in Aarhus, Denmark, was chosen secretary.

The next meeting followed in Sheffield, UK, in July 1977, in connection with the local gynecological meeting. At Bergen, Norway, in 1978, IUGA met along with the Scandinavian Congress of Obstetrics and Gynecology. In 1979 in Tokyo, IUGA met again with FIGO; this time IUGA was a special section of the program. In October 1980, IUGA met in New Orleans, organized by Jack Robertson, in connection with the newly formed Gynecological Urology Society (GUS), later to become the American Urogynecologic Society (AUGS).

The fifth IUGA meeting was held in Stockholm, September 1981, at the Wenner–Gren Center, famous for Nobel Prize presentations. The banquet was at the Royal Opera House, with a special program by the famous Swedish opera singer, Kerstin Dellert. Jack Robertson was elected president and served until 1985. Peter Sand, of Chicago, Illinois, became the general secretary. During this time, the association was growing in membership.

In the United States, Jack Robertson had found that women were being treated as second-class citizens, being examined with male instruments for their incontinence problems. An alarming number of women were incontinent after their hysterectomy surgery. Robertson devised a system of viewing the bladder using carbon dioxide instead of water. In 1968, he went to Germany and convinced the famous endoscope maker, Karl Storz, who had recently acquired the technique of fiber optics, to produce a female urethroscope to Robertson's specifications. Storz immediately liked the idea of not using water and made the first Robertson female urethroscope. Instead of just resting their instruments upon it, this was the first time doctors could view the female urethra and its pathology. This was the beginning of a pioneering path with Robertson giving seminars to physicians anxious to learn about the female urinary tract, which had not been included in their gynecological training. An immediate result was a sharp rise in the diagnoses of urethral diverticula.

The meeting was held at Santa Barbara, California, in 1982 organized by Jack Robertson and combined with the GUS, organized by Don Ostergard. In 1983, IUGA met in Mainz, Germany, and in 1984, IUGA met at the famous Breakers Hotel in West Palm Beach, Florida.

At the meeting in Budapest, Hungary, in 1985, physicians came from behind the Iron Curtain. It was vital for them to present their work at the meeting as they would rise in professional and, most importantly, pay level as a result. When one group from Poland presented a problem, the audience asked why ultrasound had not been used, which at that time would have been the obvious method of treatment. The physicians from Poland replied simply: “We do not have ultrasound.” Donald Ostergard was elected the third president and presided at the 1986 meeting at Yale University, organized by Ernest Kohorn. Don's memories include “a lot of work organizing individuals to take the financial risks to hold a meeting.”

An important event occurred at the 1986 Yale meeting. The *International Urogynecology Journal* was born. Oscar Contreras Ortiz was nominated editor in chief. Donald Ostergard became the first managing editor and, later, the editor in chief. He was followed by Linda Brubaker and now Peter

Dwyer and Paul Riss. The first issue, Volume I, was printed in September 1989 and contained the abstracts of the Riva del Garda meeting. The associate editors, section editors, and editorial board represent countries all around the world.

The 1987 meeting was in Ljubljana, Yugoslavia, organized by Bozo Kralj, of Slovenia, with 200 members worldwide. Bozo became the fourth president at the 1988 memorable meeting at Iguazu Falls, Argentina, hosted by Oscar Contreras Ortiz, where Hans Van Geelen says, “made every effort, and succeeded in strengthening social ties.” In 1989, Rodolfo Milani hosted the meeting in Riva Del Garda, Italy.

Next elected was Eckhard Petri of Germany, from 1990 to 1992, inaugurated at the Stockholm, Sweden, meeting organized by Ulf Ulmsten. Peter Dwyer says of this meeting: “One of the most low key of all the meetings, it was possibly one of the most enjoyable. It was basic but had good science. The chairman’s dinner was held in Ulf’s department at the Uppsala University cafeteria.” The 16th annual IUGA meeting was held in Sydney, Australia, in 1991, and the host and hostess were Jim and Peggy Gibson. They had a fabulous chairman’s reception that was held at the farm they owned at the time called “Stanton Hall.”

In 1992, IUGA combined with AUGS, in Boston, Massachusetts, with a lobster bake party at the famous aquarium. James Gibson, Australia, was elected sixth president. He presided the 1993 meeting in Nimes, France, which was coordinated with ICS in Rome. Gibson organized Organon to give IUGA $10,000 each year for 5 years for the best presentation at each meeting. In 1994, Harold Drutz hosted the meeting in Toronto, Canada, at which he was elected the seventh president. He presided at the Kuala Lumpur meeting in 1995 as well, hosted by Jim Gibson, which, he says, was one of the first meetings to make a profit.

In September 2–5, 1996, the meeting was in Vienna, Austria, organized by Paul Riss. This was a glorious site at which Oscar Contreras Ortiz, Buenos Aires, Argentina, was elected the eighth president. The 1997 meeting occurred in Amsterdam, arranged with the combined efforts of Hans Van Geelen, Harry Vervest, and Mark Vierhout. The meeting location was planned in Europe as FIGO was in Copenhagen. In 1998, Buenos Aires, Argentina, was the venue for IUGA, hosted by Oscar Contreras Ortiz. Linda Cardozo, London, UK, was the ninth president. In 1999, in Denver, Colorado, Willy Davila organized IUGA with Rick Schmidt of ICS to allow the first combined meeting of the two societies.

The 2000 IUGA meeting in Rome, Italy, organized by Mauro Cervini, chose Hans Van Geelen, from the Netherlands, as president. The largely attended meeting was enlivened by an audience with Pope John Paul II, celebrating the millennium year. The Pope blessed the International Urogynecology Association in his Papal address during the meeting. Hans Van Geelen recalls that at an early IUGA meeting the attendance was so small that the members could sit around one round table, discussing the clinical relevance of urodynamics. He, too, says, “in the beginning, hosting a meeting was a delicate task.”

In 2001, the IUGA meeting moved to the southern hemisphere again with Peter Dwyer as the host in Melbourne, Australia, combined with the Australian Continence Foundation. Axel Ingelman-Sundberg was awarded a lifetime achievement award, via a live television connection, at the 2001 meeting. The 2002 meeting was held in Prague, with Michael Halaska as the organizer. The river Moldau flooded the inner town, and Professor Halaska had to change the venue of the gala dinner and take out new insurance. In Prague, Peter Dwyer of Melbourne, Australia, was elected president. Peter comments that IUGA became not only a scientific society but developed a true camaraderie of friendship. He says that the young urogynecologists appreciated the emphasis on the clinic rather than the basic science (rats). Peter writes: “Presenting our own research internationally and getting ideas for our next projects was also very important, and the meetings were great fun.”

In 2003, IUGA was back in Buenos Aires, again organized by Oscar Contreras Ortiz. August 24–27, 2004, saw a spectacular meeting of IUGA in Paris, France, combined for the second time with the ICS. The chairman’s dinner held at Maxim’s Restaurant, honored Jack R. Robertson with a lifetime achievement award. The Palais Versailles was the unbelievable site of the gala dinner, hosted by Bernard Jacquetin for IUGA and Francois Haab for ICS. Paul Riss of Moedling, Austria, was elected to serve as president from 2004 to 2006. Copenhagen, Denmark, August 9–12, was the site of the 2005 IUGA meeting, organized by Gunnar Lose.

The two old friends, Axel Ingelman-Sundberg and Jack R. Robertson, met in Munich, Germany, in

August of 2004. The meeting in Copenhagen in 2005 was an exciting meeting at a unique venue with the first discussion of some of the newer mesh kits. In 2006, the annual IUGA meeting was in the beautiful historic city of Athens, with many social events being held at some of the ancient historic sites. Professor Oscar Contreras Ortiz received a prestigious lifetime achievement award. 2007 found us back across the Atlantic in Cancun Mexico with a stunning gala dinner at sunset on the beach. At the Cancun meeting, Professor Donald Ostergard received a lifetime achievement award. Despite difficult weather caused by a number of typhoons, many were still able to attend the 2008 meeting in Taipei, where Professor Harold Drutz received a lifetime achievement award from the IUGA for his ongoing contributions to the society (including the only Canadian to have been president of the society, in 1994–1996). The stunning venue of Lake Como, Italy, was the site for the 2009 meeting, where Professor Jim Gibson received a lifetime achievement award. 2010 saw another joint meeting of the ICS and IUGA hosted by Professors Drutz and Herschorn in Toronto, Canada.

The 2011 IUGA meeting moved back to Europe and was held in Lisbon, Portugal. 2012 led the IUGA meeting back to beautiful Brisbane, Australia. In 2013, Dublin hosted a wonderfully successful meeting and Linda Cardozo received a lifetime achievement award. In 2014, IUGA joined with AUGS in Washington, DC, to host a great meeting where 61 countries were represented.

UROGYNECOLOGY TRAINING PROGRAMS

Urogynecology training programs have grown internationally with support from the IUGA. Recognition and accreditation of urogynecology and pelvic floor reconstruction has also progressed significantly with formal subspecialty certification programs now in many countries. The detailed progress and trainees of some of the larger subspecialty training programs are given in the appendix.

PROGRESS IN THE TWENTIETH AND TWENTY-FIRST CENTURIES

Treatment

Marion Sims, in the United States, was one of the first to establish the relationship of urology and gynecology. Determined to cure vesicovaginal fistulas, he finally used silver wire and announced in 1852 the cure of 252 out of 320 attempts. Howard A. Kelly, the first professor of gynecology at the Johns Hopkins Medical School, believed that gynecology and urology were so closely related that a physician could not be trained in either field and ignore the other. In 1893, he invented a cystoscope and was the first person to insert ureteral catheters under direct vision. Kelly’s successor, Guy Hunner, described Hunner’s ulcer, which today is called interstitial cystitis. Succeeding Hunner was Houston Everett, whose contribution was the relationship of the urinary tract to cervical cancer. In 1914, Latzko perfected the cure of posthysterectomy vesical vaginal fistula. Next, Richard TeLinde added water endoscopy to the Hopkins female urology program. Most teaching programs at the time gave little or no exposure to female urology [2].

In 1892, Poussan proposed the concept of urethral advancement for the management of urinary incontinence [5]. He suggested, “introducing a bougie into the urethra, resecting the external meatus and portion of the urethra, and then after torsion of the canal to one hundred and eighty degrees, it is transplanted to a point just below the clitoris.” By the turn of the century, four main treatments for stress urinary incontinence were outlined:

1. Injection of paraffin into the region of the urethra
2. Massage and electricity
3. Torsion of the urethra
4. Advancement of the external urethral meatus

A century later, we are still trying to identify the best urethral bulking agent. Although it is no longer paraffin, research with Teflon (poly [tetrafluorothene]), silicone, collagen, autologous fat, hyaluronic acid, carbon particles, and various copolymers has failed to identify an ideal medium.

In his landmark paper in 1913, Kelly outlined operations for managing urinary incontinence in women [6]. These included the following:

- Puncture of the bladder and insertion of a catheter
- Closing the urethra and creating a vesicoabdominal fistula

- Closing the vagina and creating a rectovaginal fistula
- Compression of the urethra with an anterior colporrhaphy
- Periurethral injection of paraffin
- Advancement of the urethral meatus to the clitoris

Kelly suggested that “the torn or relaxed tissues of the vesical neck should be sutured together using two or three vertical mattress sutures of fine silk linen passed from side to side.” In his first publication, he described 16 patients as being well and 4 patients in whom the procedure was not successful, giving a success rate of 80%. However, further evaluation has revealed that the long-term success, using only these sutures to correct stress incontinence, falls to roughly 60% [7]. This decline is possibly related to gradual postoperative elongation of the smooth muscle in which the sutures were placed [8]. With coincident suburethral plication of the pubourethrovaginal ligaments of the urogenital diaphragm, the long-term results of a Kelly plication are significantly better [9].

Sling procedures were pioneered in the early 1900s by three European physicians. Goebell first suggested transplantation of the pyramidalis muscle in 1910 [10]. This was followed by Frankenheim who, in 1914, recommended using the pyramidalis or strips of rectus muscle as a suburethral sling by attaching the muscle to overlying fascia [11]. In 1917, Stoeckel suggested combining the techniques of Goebell and Frankenheim and adding plication of the vesical neck [12]. Throughout the twentieth century, there have been many variations of sling procedures described in the literature. In 1907, Giordano suggested the use of the gracilis muscle by wrapping it around the urethra [13]. Shortly thereafter, in 1911, Squier described the use of the levator ani muscles by placing them between the vagina and urethra [14], and, in 1923, Thompson recommended the use of strips of the rectus muscle, surrounded by fascia, to be passed in front of the pubic bones and around the urethra [15]. The next key event in the development of surgery to the anterior compartment was the development of the bulbocavernosus muscle fat pad graft by Martius in 1929 [16]. This has found wide use in fistula repairs and reconstruction of the anterior vaginal wall. In 1968, John Chasser Moir [17] introduced the concept of the gauze hammock operation as a modification of the original Aldridge [18] sling procedure described in 1942. Chasser Moir recognized that “operations of this type do no more than support the bladder neck and urethrovesical junction and so prevent the undue descent of parts when the woman strains or coughs.”

Victor Bonney, in 1923, stated, “incontinence depends in some way upon a sudden and abnormal displacement of the urethra and urethrovesical junction immediately behind the symphysis” [19]. This was followed in 1924 by a description from B.P. Watson of “the muscle sheet that normally supports the base and neck of the bladder” and his statement that “so far as the incontinence of urine is concerned, the important sutures are those which overlap the fascia at the neck of the bladder and so restore it to its normal position.” In reviewing Watson’s work with anterior colporrhaphy, he was able to obtain “perfect control” in 65.7% of cases, “improvement” in 21.9%, and “no success” in 12.4% [20]. These figures are in keeping with others that have been reported for anterior colporrhaphy. Therefore, it was apparent that hypermobility of the bladder neck was an issue and that the anterior colporrhaphy was not a satisfactory operation for stress incontinence.

The next landmark in genitourinary surgery occurred in 1949 with the publishing of the paper of Marshall, Marchetti, and Krantz on “The correction of stress incontinence by simple vesicourethral suspension.” They suggested that this operation was “particularly valuable for patients whose first procedure failed.” In their first 44 patients, they described 82% of patients with excellent results, 7% with improvement, and an 11% failure rate [21]. Shortly thereafter, in 1950, H.H. Fouracre Barns described the “round ligament sling operation for stress incontinence”; this technique was popularized by Paul Hodgkinson [22]. In 1961, John Burch first described his modification of the Marshall–Marchetti–Krantz procedure, which involved a retropubic colpourethropexy that took the anterolateral aspects of the vault of the vagina and attached them to Cooper’s ligament [23]. Burch recognized the potential complications of this procedure if done alone including the creation of an enterocele or rectocele, the development of ventral/incisional hernias, and even the possibility of a vesicovaginal fistula.

Diagnosis and Investigation

As the number of procedures offered for the treatment of stress incontinence increased, there were also significant advances in the urogynecological diagnostic procedures available. In 1882, Mosso and Pellacani described cystometry using a smoked drum and a water manometer [24]. An aneroid barometer for cystometric evaluation was developed by Lewis in 1939 [25]. Jeffcoate and Roberts, in 1952, introduced the concept of radiographic changes in the posterior urethrovesical angle [26]. These changes were further modified in 1956 by Bailey in England, who described seven variations in the urethrovesical angle on radiographic studies [27]. Later modifications were performed by Tom Green in the United States in 1962, when he described Green types 1 and 2 incontinence [28]. Identification of the posterior urethrovesical angle by lateral bead chain cystography was introduced by Hodgkinson in 1953 [29].

By 1956, Von Garrelts had introduced the concept of uroflowmetry [30]. In 1964, Enhorning, Miller, and Hinman combined cystometry with radiographic screening of the bladder [31]; this was followed a few years later in 1969 by Brown and Wickham's introduction of urethral pressure profilometry [32]. Another landmark occurred in 1971, when Patrick Bates, Sir Richard Turner-Warwick, and Graham Whiteside introduced synchronous cine pressure–flow cystography, with pressure and flow studies [33]. This was the beginning of the field of video urodynamics. Equipment was further expanded with the introduction of the microtip transducer in 1975 by Asmussen and Ulmsten, for measuring urethral closure pressure [34].

Further investigational advances occurred in the latter part of the twentieth century. These included the introduction of the Urilos monitor in 1974 by James et al. [35]. This device allowed evaluation of the symptom of dampness for whether the fluid lost was urine. In 1981, Sutherst et al. developed the pad-weighing test as an objective measure of the severity of urinary incontinence [36].

In 1961, Enhorning suggested that "surgical treatment for stress incontinence is probably mainly beneficial because it restores the neck of the bladder and the upper part of the urethra to the influence of intra-abdominal pressure" [37]. This introduced the concept of pressure transmission ratios and the idea that successful operations for stress urinary incontinence worked by restoring the urethrovesical junction to an intra-abdominal position. In 1956, Jeffcoate added further interpretation of our investigative techniques when he attempted to caution gynecologists by stating "the absence of the posterior urethrovesical angle is merely a sign of incompetence of the internal sphincter. The presence of an angle is a function of the involuntary muscle at the urethrovesical junction, not of the muscle of the pelvic floor" [38]. And so the simplistic approach of static cystourethrograms began to be questioned. Green had suggested that if one saw a radiographic diagnosis of type 1 incontinence, this could readily be repaired with an anterior colporrhaphy; the type 2 stress incontinence required a retropubic urethropexy. A number of authors, including Drutz in 1978 [39], have confirmed the limited accuracy of static cystourethrograms.

By 1953, Paul Hodgkinson had recommended "that if on anteroposterior straining radiograph, the urethrovesical junction is depressed 4 cm below the lower border of the symphysis, I believe the objective of the operation can be accomplished through anterior colporrhaphy" [28]. A decade later, Hodgkinson commented on the frequency of detrusor dyssynergia, with grade 1 defined as a detrusor contraction in response to coughing and heel jouncing and grade 2 a spontaneous automatic detrusor contractility when recumbent. Hodgkinson recognized the importance of discovering this condition prior to performing any surgery for stress urinary incontinence [40].

Success Rates

As we approached the 1970s, we began to recognize that operative failures in the treatment of stress urinary incontinence involve three areas [41] as follows:

1. Incorrect diagnosis and the fact that bladder instability (and not just simple stress incontinence) may have been the cause of the incontinence.
2. The wrong operation may have been chosen and some operations probably give better long-term results.
3. The concept of technical failure.

We recognized that the vaginal approach to primary stress incontinence probably only gave a 50%–60% success rate, whereas the suprapubic approach gave success rates of at least 80%. Morgan, in 1973, discussed indications for primary retropubic urethropexy: these included minimal pelvic floor relaxation, chronic chest disease, occupations involving heavy lifting patients who were heavily involved in athletics, and obesity [42]. In 1970, Hodgkinson stated that “the most durable operation for stress incontinence is a retropubic urethropexy and the least durable is a vaginal repair.” Hodgkinson quoted a 92.1% success rate with his own 404 patients that had retropubic urethropexy [40]. The other movement in the 1970s was of the urologists and gynecologists toward endoscopic bladder-neck suspensions such as the Pereyra, Raz, and Stamey suspensions; numerous variations including the Gittes and Cobb–Raagde were described in the literature. In the 1990s, we have now realized that the long-term results of these needle suspension procedures are also not as good as the retropubic procedures.

The 1990s have also seen the advent of minimally invasive sling procedures for stress urinary incontinence. The first of these, the tension-free vaginal tape and the concomitant integral theory of the pathophysiology of incontinence were described by Ulmsten and Petros in the early 1990s [43,44]. There are now multiple variations of this procedure including the transobturator approach. Success rates are reported to be similar to that of the Burch repair [45]. More recently, single-incision midurethral slings have been advocated. The long-term success of these new procedures is yet to be established.

The great champion of pelvic floor exercises, Arnold Kegel, reported pre- and postoperative benefits of the properly performed exercises [46]. Unfortunately, many patients are placed on this regimen only after an unsuccessful surgical procedure. Robertson, with Bergman and Elia, in 2004, has described an enhancement of Kegel exercises, when done in a magnetic field, combined with DeLancey’s “knack procedure,” to give support to the urethra when it is most needed [47].

THE WAY AHEAD

Now in the twenty-first century, we must consider what lies ahead. The main fields of responsibility as urogynecologists and reconstructive pelvic surgeons include the following:

- Education
- Surgery
- Uropharmacology
- Neurophysiology
- Behavior modification
- Collagen
- Ultrasonography/magnetic resonance imaging (MRI)
- Stem cells
- Graft materials

Regarding education, we need to focus on education of our colleagues in obstetrics and gynecology, family practice, geriatrics, and community health care, of allied health professionals such as nursing and physiotherapy, and of the public. The awareness must be increased that incontinence is not a normal effect of aging; the many myths including “everyone gets it” and “it can’t be treated” must be dispelled. Urogenital aging must be stressed as part of menopause management, and conservative management in the community should be promoted. The other aspect of education is the training of new subspecialists in the field of urogynecology and reconstructive pelvic surgery. Board certification is now available in Australia and in the United States. IUGA is now establishing international standards for training in conjunction with FIGO and WHO.

Within the field of surgery for pelvic floor problems, we need to reevaluate what we do. Over 200 operations have been described for stress incontinence. Randomized controlled trials, with adequate patient numbers and follow-up of at least 2 years, are required for evaluation of new and existing procedures. The role of bulking agents is still controversial and the ideal medium has yet to be discovered. A variety of fascia and mesh is available for use in pelvic floor reconstructive procedures; however, the long-term durability and consequences of these are still unknown. This includes many new mesh devices and kits for pelvic floor reconstruction. Concerns have been raised about the ethics of some of these newer mesh devices [48]. New pharmacologic agents continue to be produced; well-designed, placebo-controlled trials are mandatory for their evaluation. Neurophysiology is another developing area; work is being done to determine if there are certain factors in labor that lead to irreversible changes to the pelvic floor. Other questions that have been raised include whether abnormalities in the electromyographic patterns predict success or failure of different treatments. We continue to develop new modes of conservative management including behavior modification and devices; further studies are needed to clarify the specific areas of use for these therapies.

The role of collagen in pelvic floor disorders is a fascinating area. We need effective, qualitative, and quantitative assays to determine whether there are certain defects of collagen in patients with pelvic floor dysfunction. Also, we need to establish whether there may be potential genetic markers that may be screened for to determine certain “at-risk” patients. Perhaps there exists a select group of patients that should be counseled to have delivery by cesarean section; this group may also require the use of synthetic materials in reconstruction of their pelvic floor. We need to look at the relationship of collagen to estrogen and the general effects of urogenital aging to see if they are independent factors. Research into genetic components of pelvic floor prolapse is exciting. At Mount Sinai Hospital in Toronto, Dr. May Alarab and her associates have shown that genes that both promote the buildup of extracellular matrix and cause its degradation are different in premenopausal women with prolapse compared to controls.

We are in the midst of a revolution in imaging and diagnostic technology. The development of 3D ultrasound [49] and the progress with MRI have allowed a new approach to evaluating defects associated with stress urinary incontinence and pelvic floor disorders. Progress in the field of ultrasound has been hampered by a lack of standardization of terminology; this was recognized by the German Association of Urogynecology, who attempted to make recommendations for standardization of methodology [50]. The fact that different methods are used (such as abdominal, perineal, introital, vaginal, and rectal) has further impeded progress in this field. Recent papers have investigated the urethra and surrounding tissues with intraurethral ultrasonography; the authors have proposed that sphincter measurements can be a prognostic factor in patients who underwent operations for stress urinary incontinence [51]. Beco stated that “Doppler and colour studies will play and increasing role in the evaluation of urethrovesical disorders” (J. Beco, personal communication, November 1996). With new developments in MRI and especially dynamic MRI, these techniques will also play a growing role in investigation and research. New ways of investigating urethral function are also appearing with the introduction of the MoniTorr device and measurement of urethral retro-resistance [52].

The difficulties of introducing new graft materials into pelvic floor reconstructive surgery have highlighted the need for careful research and long-term follow-up with all innovative technologies. Stem cell research may introduce a natural type of treatment for stress urinary incontinence that replaces bulking agents.

There is an increasing focus on quality of life tools as a research outcome. National and international societies must continue to promote and support research in the field to advance pelvic floor health for women.

CONCLUSIONS

At the International Continence Society meeting in 1986, Sir Richard Turner-Warwick gave an address in which he defined the urogynecologist as “neither the general urologist nor the general obstetrician and gynecologist, but someone who has special training and expertise in genitourinary problems in women” [53]. Today, we should expand this definition to include urogynecology and reconstructive pelvic surgery. Such a physician implies a surgeon with specialized training in the conservative and surgical management of women with urinary and/or fecal incontinence, persistent genitourinary complaints, and disorders of pelvic floor supports.

As Marcel Proust said, “We must never be afraid to go too far, for the truth lies beyond.” We must humbly accept that the “truths” that we identify today certainly will have to be changed in the future. However, if we work collaboratively to produce well-designed scientific research, we should be able to establish truths that stand the test of time in our ongoing quest to improve the quality of life for women with pelvic floor problems.

ACKNOWLEDGMENTS

This chapter includes major segments of text adapted from the IUGA presidential address given by Professor Harold Drutz at the 21st Annual Meeting of the International Urogynecological Association held in Vienna in 1996. The text was later published: Drutz HP. The first century of urogynecology and

reconstructive pelvic surgery: Where do we go from here? *Int Urogynecol J* 1996; 7: 348–353.

We thank professors Stanton, Cardozo, Ostergard, and Drutz for providing information on their trainees.

Trainees of Professor Linda Cardozo, Their Work as a Research Fellow, and Their Current Practice Locations

(Professor Cardozo was Professor Stanton’s first trainee.)

1983–1985	*Dr. Eboo Versi*: Studied urinary symptoms and urodynamic findings in climacteric women. Associate professor of urogynecology, Harvard Medical School, Boston, USA. Now working in the pharmaceutical industry.
1985–1987	*Mr. Andrew Tapp*: Compared physiotherapy to surgery in the treatment of genuine stress incontinence. Now consultant obstetrician and gynecologist, Shrewsbury.
1987–1989	*Mr. Christian Barnick*: Studied electromyography of the urethral sphincter in various groups of women. Now consultant obstetrician and gynecologist at the Homerton Hospital, London.
1988–1990	*Mr. Christopher Benness*: Assessed the efficacy of vaginal estradiol pellets in the management of postmenopausal urinary urgency (MD 1995). Now consultant at Royal Prince Alfred Hospital, Sydney, Australia with subspecialty accreditation in urogynecology.
1989–1991	*Mr. Alfred Cutner*: Studied the effect of pregnancy on the lower urinary tract (MD 1993). Now consultant gynecologist at the University College Hospital, London.

1990–1991	*Mr. Gilbert Burton*: Studied toilet training habits (MD 1994). Now consultant at North Shore Hospital, Sydney, Australia, with subspecialty accreditation in urogynecology.
1990–1992	*Mr. Brian Wise*: Evaluated maximal electrical stimulation in the management of detrusor instability (MD 1996). Now consultant obstetrician and gynecologist, Ashford, Kent.
1991–1994	*Mr. Cornelius Kelleher*: Studied the effect of urinary incontinence and its management on the quality of life of women (MD 1996). Now consultant obstetrician and gynecologist at St Thomas's Hospital, London.
1992–1994	*Mr. Vikram Khullar:* Evaluation of ultrasound and Doppler blood flow measurements in the assessment of incontinent women (MD 1999). Subspecialty trainee urogynecology, King's Healthcare Trust, 1997–2000. Currently the consultant in urogynecology at St Mary's Hospital, London.
1993–1995	*Mr. Simon Hill*: Investigated the management of women with nocturia. Currently consultant obstetrician and gynecologist and medical director at Blackburn District General Hospital.
1994–1996	*Mrs. Carmel Ramage (Gleeson)*: Combined project with Professor Christopher Fry, Institute of Urology, London, assessing the Na^+ ion pump in the detrusor muscle. Currently consultant obstetrician and gynecologist, Bradford.
1994–1996	*Mr. Stavros Athanasiou*: Undertook ultrasound assessment of the pelvic floor in women with prolapse and incontinence (MD 1998). Returned to practice with a university appointment in Athens, Greece.
1995–1997	*Mr. Philip Toozs-Hobson*: "Three dimensional ultrasound assessment of damage to the urethral and anal sphincters following childbirth" (MD 2002). Now consultant obstetrician and gynecologist at Women's Hospital, Birmingham.
1995–1998	*Mr. Kelvin Boos*: Studied devices for the management of genuine stress incontinence (MD 2001). Appointed consultant obstetrician and gynecologist, Brighton. Now returned to Ireland.
1996–1999	*Mr. Andrew Hextall*: Studied the effect of estrogens on urinary symptoms in postmenopausal women (MD 2001). Now consultant obstetrician and gynecologist, West Hertfordshire.
1997–1998	*Mr. Alex Yip*: Overseas fellow returned to Singapore to both academic and private practice.
1997–2000	*Mr. John Bidmead*: Studied physiotherapy and novel surgical techniques for stress incontinence. Subspecialty trainee, 2000–2002. Consultant urogynecologist, King's College Hospital.
1999–2000	*Ms. Katie Clifford*: Fellow on secondment from St Mary's Hospital, currently a consultant at Imperial, London.
1999–2002	*Mr. Dudley Robinson*: Studied the use of antidiuretics in the management of incontinence. Subspecialty trainee, 2002–2004 (MD 2006). Consultant urogynecologist at King's College Hospital.
2000–2002	*Mrs. Jane Rufford (Bailey)*: Studied minimally invasive surgery, surgery for stress incontinence. Currently consultant gynecologist (part time) at King's College Hospital.
2001–2004	*Mr. James Bamforth*: Studied the effect of prolapse on quality of life in the elderly. Subspecialty trainee urogynecology. King's College Hospital (2004–2006). Now consultant obstetrician and gynecologist, Bournemouth.
2002	*Mr. Piet Hinoul*: Overseas fellow from Belgium returned initially to clinical urogynecology, now working in a senior medical post with Johnson & Johnson.
2002–2005	*Mr. Matthew Parsons*: Studied the use of a computerized bladder diary (MD 2009). Now consultant obstetrician and gynecologist, Birmingham Women's Hospital.
2004–2007	*Ms. Maria Vella*: Studied incontinence in women with cystic fibrosis. Currently a trainee, South East Thames. Now consultant obstetrician and urogynecologist, Bury St Edmonds.
2005–2008	*Mr. Rufus Cartwright*: Studied the oxybutynin patch and its effect on quality of life (MD 2010). Currently a trainee at North Thames. Undertaking further research for a PhD on an MRC grant.
2005–2006	*Ms. Sushma Srikrishna*: Studied patient-orientated goals in relation to pelvic floor reconstructive surgery. Subspecialty trainee, 2006–2008. Currently consultant obstetrician and urogynecologist, King's College Hospital.
2006–2007	*Mr. Arther Tseng*: Visiting fellow in Singapore, now a consultant urogynecologist in Singapore.
2007–2009	*Ms. Arasee Rangenathan*: Studied the effect of new drugs on the bladder and urethra. Now consultant obstetrician and gynecologist, Sidcup Hospital.
2008	*Mr. Luigi Erricello*: Overseas fellow from Italy now practicing in Italy.
2008–2010	*Mr. Ismaiel Abu-Mahfouz*: Studied ultrasound bladder wall thickness. Returned to Jordan.
2009–2010	*Mrs. Monika Vij*: Returned to West Midlands, now a subspecialty trainee in urogynecology, Bristol.
2009	*Mr. Marco Torella*: Visiting fellow in Italy, now working in Italy.
2010–onward	*Ms. Heleni Mastoroudes*: Studying the management of rectoceles. Returned to clinical training in the South East Thames rotation.

2010	*Mr. Guy Mozogo*: Visiting fellow in France, returned to clinical practice.
2010–onward	*Mr. Ilias Giarenas*: Studying invasive investigative techniques for women with lower urinary tract symptoms, currently subspecialty trainee in urogynecology at King's College Hospital, studying combination therapy for the overactive bladder.
2011	*Ms. Isabelle Freilling*: Visiting fellow from Sweden, returned to clinical practice.
2012	*Mr. Ki Hoon Ahn*: Visiting fellow from Korea, returned to clinical practice.
2012–2013	*Mr. Lanka Abeywickrama*: Clinical research fellow, returned to clinical practice in West Midlands.
2013–onward	*Mr. Ganesh Thiagamoorthy*: Studying common interventions used in association with pelvic floor surgery, current fellow.
2013–onward	*Mr. Martino Zecche*: Currently in a fellow post.
2013	*Ms. Maria Grazia Matarazzo*: Visiting fellow in Italy, now returned to clinical practice in Italy.

Trainees of Professor Donald Ostergard and Their Practice Locations

1978–1979	*Tom McCarthy*: UCSF Medical School to private practice (now deceased).
1979–1980	*Narender Bhatia*: Professor at UCLA Medical School, director of the Urogynecology Fellowship Training Program with over 35 fellows trained, Long Beach, CA.
1980–1981	*David Hebert*: Tulane Medical School to private practice, Los Angeles.
1981–1982	*Alfred Bent*: Professor in several medical schools, director of the Fellowship Training Program with over 30 fellows trained, retired in Halifax, Nova Scotia.
1981–1982	*David Richardson*: Professor, director of Fellowship Training Program, Detroit, MI.
1982–1983	*Richard Scotti*: Professor in several medical schools, director of the Fellowship Training Program with over 20 fellows trained (now deceased).
1982–1983	*Jerry Benzl*: Private practice, Mission Viejo, CA.
1983–1984	*Larry Francis*: Private practice, San Bernardino, CA.
1983–1984	*Larry Cutner*: Private practice, Long Beach, CA.
1984–1985	*Larry Bowen*: Private practice, Sacramento, CA.
1984–1986	*Peter Sand*: Professor, Fellowship Program director with approximately 10 fellows trained, Chicago, IL.
1985–1986	*Jody Blanco*: Professor, Cornell, NY.
1986–1987	*Nicolette Horbach*: Professor to private practice, Arlington, VA.
1986–1987	*Jeff Cornella*: Professor, director of the Fellowship Training Program with over 15 fellows trained, Phoenix, AZ.
1987–1988	*Robby Summitt*: Professor, now private practice, Memphis, TN.
1987–1988	*Toni Harris*: Academic, University of California, Davis, CA.
1988–1989	*Joe Montella*: Professor, University of Philadelphia, Philadelphia, PA.
1988–1989	*Lisa Hirsch*: Private practice, Newport Beach, CA.
1989–1990	*Scott Farrell*: Academic practice, has trained several fellows, Halifax, Nova Scotia.
1989–1990	*Hilary Cholhan*: Professor, director of the Fellowship Training Program with over seven fellows trained. Now private practice, Buffalo, NY.
1990–1991	*Jorge Peacher*: Private practice, San Antonio, TX.
1990–1991	*Karl Luber*: Private practice, faculty, Fellowship Training Program, San Diego, CA.
1991–1992	*Michael Weinberger*: Academic to private practice, Los Angeles, CA.
1992–1994	*Janine Jensen*: Academic to private practice, Long Beach, CA.
1991–1993	*Steve Swift*: Professor, director of the Fellowship Training Program with approximately 15 fellows trained, Charleston, SC.
1993–1995	*Victoria Handa*: Professor, Johns Hopkins University; director of the Fellowship Training Program, Baltimore, MD.
1994–1996	*Michelle Germain*: Private practice, Baltimore, MD.
1995–1998	*Karen Noblett*: Professor, director/faculty of the Fellowship Training Program, University of California, Irvine, CA.
1996–1999	*Jack Devine*: Private practice, Akron, OH.
1998–2001	*Andrew Cassidenti*: Clinical professor at USC, private practice, Mission Viejo, CA.
1999–2002	*Stacey Wallach*: Professor, University of California, Davis, CA.
2001–2004	*Laurie Kane*: Private practice, Delaware.

2002–2005	*Melissa Huggins*: Private practice, Providence, RI.
2004–2007	*Tam Le*: Private practice, faculty, Fellowship Training Program, Los Angeles, CA.
2005–2008	*Leanne Kon*: Private practice, Los Angeles, CA.
2007–2008	*Alex Shapiro*: Private practice, Denver, CO.
2008–2009	*Jill Hall*: Private Practice, Oxnard, CA.
2008–2011	*Hiren Patel*: Academic, University of California, Irvine, CA.
2009–2011	*Gina Sternschuss*: Private practice, Upper Michigan.
2011–2013	*Lioudmila Lipiskaia*: Academic, Buffalo, NY.
2011–2012	*Ali Azadi*: Academic to private practice, Louisville, KY.
2013–2014	*Christina Truong*: Academic, UCLA, Torrance, CA.

Trainees of Professor Harold Drutz and Their Practice Locations

1980–1981	*Abrahim Shamai*: Rambam Hospital Israel.
1986–1989	*Thomas Mainprize*: Fellowship director in Calgary, then chair of the Department of Obstetrics and Gynecology, Saskatoon, Canada.
1990	*Jae Yup-Hong*: University of Korea, Seoul, Korea.
1989–1990	*Kevin Baker*: University of Ottawa, Ottawa, Canada.
1989–1990	*Douglas Torraville*: Corner Brook, Newfoundland, Canada.
1990–1991	*Marie-Claude Lemieux*: Head of obstetrics and gynecology, Maisonneuve, Rosemont, Montreal, Canada.
1991–1992	*Elaine Demarcousa*: New York City, USA.
1991–1992	*Clive Spence Jones*: London, UK
1992–1993	*Cathy Flood*: Created the division of urogynecology at the University of Alberta and was the director from 1993 to 2008, fellowship director of urogynecology, Edmonton, Canada.
1992–1994	*Patricia Lee*: Head urogynecologist at the Sunnybrook Hospital, Toronto, Canada.
1993–1994	*Paul Hardiman*: Hammersmith, UK.
1994–1996	*J. Barry MacMillan*: Head of urogynecology, University of Western Ontario, London, Canada.
1994–1996	*Robert Verhoest*: New York, USA.
1996–1998	*Bunan Alnaif*: Trainee from Canada and Iraq, now practicing in Vanderbilt, USA.
1996–1998	*Fons Amaye-Obu*: New York, USA, and Nigeria.
1997–1998	*Ian Currie*: Buckinghamshire, UK.
1997–1999	*Kevin Smith*: Reading, UK.
1998–1999	*Jane Schulz*: Divisional director of urogynecology, Edmonton, Canada.
1999–2000	*Corrinne Jabs*: Regina, Canada.
1999–2001	*Danny Lovatsis*: Mount Sinai Hospital, Toronto, Canada.
1999–2001	*Joyce Schachter*: Ottawa, Canada.
1999–2001	*Dana Soroka*: St. Michael’s Hospital, Toronto, Canada.
2001–2002	*Fatma Noorwali*: Saudi Arabia.
2001–2003	*Ahmed Al-Badr*: Head of urogynecology at King Fahad Medical City, Saudi Arabia.
2002–2004	*Vatche Minassian*: Trainee from Lebanon and the United States, head of urogynecology at Harvard Medical School, Boston, USA.
2003–2005	*Dante Pascali*: Head of urogynecology, University of Ottawa, Canada.
2004–2006	*May Alarab*: Trainee from Iraq and Ireland, practicing at Mount Sinai Hospital, Toronto, Canada.
2004–2005	*Kenneth Maslow*: University of Manitoba, Winnipeg, Canada.
2006–2009	*Jennifer Jose*: Makati Hospital, Manila, Philippines.
2006–2009	*Lamya Al-Kharusi*: Head of urogynecology, Muscat, Oman.
2007–2010	*Maria Bortolini*: Head of basic science research, Sao Paulo, Brazil.
2007–2009	*Raed Sayed Ahmed*: Saudi Arabia.
2007–2009	*Danny Kreichman*: North York General Hospital, Toronto, Canada.
2007–2010	*Victor Miranda*: Santiago, Chile.

2 Epidemiology: United States

Ananias C. Diokno, Scott E. Kalinowski, and Benjamin J. Girdler

INTRODUCTION

Epidemiology, the study of the relationships of various factors determining the frequency and distribution of diseases in a community [1], as applied to the study of urinary incontinence (UI), has advanced over the past several years. However, most of these studies are cross-sectional. A need exists for more longitudinal studies to evaluate the incidence, remission, risk factors, and prevention of this disease process. The methodologies to evaluate the epidemiology of UI vary greatly. Furthermore, there is no consensus on the definition of UI among investigators dealing with this subject. Consequently, there is conflicting information, especially in the prevalence rates. Another major issue in studying UI is the fact that incontinence itself is a condition with many varied types, which can be transient and which can occur in many different segments of the population. Students of the epidemiology of UI must therefore account for all these variables when evaluating data from these studies.

PREVALENCE OF UI

Prevalence of UI is defined as the probability of being incontinent within a defined population group during a specific period. In 1983, Diokno et al. created the first comprehensive epidemiological study of incontinence in the United States [2]. The Medical, Epidemiologic, and Social Aspects of Aging (MESA) study showed the prevalence of incontinence among women 60 years and older living in the community to be 38%.

A recent cross-sectional analyses using data from the 2008 Nurses' Health Study among participants age 62–87 years revealed a prevalence of urine leakage at least once per month to be 38%, 7% fecal incontinence alone, and 7% dual incontinence [3].

UI prevalence in nursing homes is even higher. Offermans et al. [4] reported the prevalence rates based on analyzing 16 reported studies. The prevalence rate was reported to range from 43% to 77% (median 58%).

The prevalence of UI in women increases with age. A postal survey was conducted by Thomas et al. [5]. Incontinence was subdivided into regular UI for a loss twice or more per month and occasional for less than twice per month. Table 2.1 shows the prevalence rates for regular and occasional incontinence in women aged 15 to more than 85 years.

Several studies have investigated incontinence in women of different races and found intriguing results. Lower rates of stress and mixed incontinence were reported by African-American women when compared with white women [3,6]. Hispanic and Asian-American women have been shown to have equivalent urodynamic stress incontinence rates to white women, whereas the African-American women had higher rates of detrusor overactivity than the other three groups [7]. African-American women were found to have statistically significant smaller bladder capacities, smaller maximum cystometric capacities, and higher maximum urethral closure pressures compared to Caucasians [8]. Fenner et al. looked at the incontinence rates in African-American and Caucasian women in southeastern Michigan. They observed similar racial differences in prevalence, type, and quantity of urine loss but failed to find support for the belief that risk factors for UI differed between Caucasian and African-American women [9].

INCIDENCE AND REMISSION

Incidence is the probability of becoming incontinent during a defined period of time. Determining the incidence of a condition or disease is helpful in determining the onset of the condition as well as in understanding the risk factors of the condition. The MESA survey established the incidence rate of UI in the United States [10]. The incidence rate among women who were continent during the initial baseline interview and became incontinent a year later was 22.4%. For those who remained continent at the 1-year follow-up visit, the incidence in the second year of follow-up was 20.2%. Hagglund et al. found a mean 4% annual incidence rate of UI reporting on a Swedish community of 10,500 inhabitants aged between 22 and 50 years [11]. An annual incidence rate of 6.3% for people greater than or equal to 40 years old was found in McGrother et al.'s study in the United Kingdom [12]. Two thousand twenty-five women older than 65 years in rural Iowa were evaluated by Nygaard and Lemke. The 3-year incidence rate for urge incontinence and stress incontinence were 28.5% and 28.6%, respectively [13]. Maserejian et al. reported the incision of UI based on the Boston Area Community Health Survey (BACH) of 3201 women age 30–79 years. They reported the incidence of UI at least monthly to be 17.1% and weekly 8%–9%. Among women with weekly baseline UI, 41.7% continued to report weekly UI, 14.1% monthly UI, and 44.2% had complete remission [14].

The MESA survey also analyzed the remission rate for UI. The remission rate—that is, women who were incontinent at the baseline (first) interview and became continent during the second interview a year later—was 11.2%. A similar rate (13.3%) of incontinent respondents at the second interview reported being continent a year later at the third interview. Hagglund et al. reported a 4% mean annual remission rate in the same Swedish community mentioned earlier [11]. Nygaard and Lemke's 3-year remission rates for urge and stress incontinence were 22.1% and 25.1%, respectively [13]. Townsend et al. looked at remission rates in 64,650 women 36–55 years of age participating in the Nurses' Health Study II. They reported remission rates of 13.9% at 2-year follow-up. However, when the group was further delineated by age group, they found significantly higher remission rates in women 36–45 years of age when compared to those 46–55 years of age (17.1% vs. 11.9%) [15].

Table 2.1 Prevalence of Urinary Incontinence in Women

Years	Regular UI (%)	Occasional UI (%)	Total UI (%)
15–24	4.0	11.9	15.9
25–34	5.5	20.0	25.5
35–44	10.2	20.7	30.9
45–54	11.8	21.9	32.9
55–64	11.9	18.6	30.5
65–74	8.8	14.6	22.4
75–84	16.0	13.6	29.6
>85	16.2	16.2	32.4

Source: Offermans MP et al., *Neurourol Urodyn*, 28(4), 288, 2009.

These findings suggest a proportion of women affected by UI will improve over time without intervention. Because UI can be affected by many factors such as acute illness, seasonal changes, and fluctuating medical illnesses, it can be assumed that when questioned longitudinally many women would report varying degrees and prevalence of incontinence. Implying that for many patients, UI is not necessarily a progressive condition but rather a dynamic process that may come and go with or without medical or surgical intervention. Further studies are needed to determine factors that may predict which respondents tend to have remission and which tend to persist or progress. It is also important to consider the possibility of spontaneous remission when reviewing "cure" rates reported in treatment trials and to discuss the possibility of remission/recurrence when counseling patients.

TYPES AND SEVERITY OF UI

Prevalence and Incidence of Types of UI

In epidemiological studies, as in clinical investigations, the type of UI must be defined. In general, incontinence is considered to be of the stress type when the urine loss was experienced at the time of physical exertion (such as coughing, laughing, sneezing). Urge incontinence is defined as involuntary loss of urine preceded by a sudden urge to void. When the urine loss is associated with both stress and urge, it is considered to be of the mixed type. Because of the difficulty in identifying the overflow type, when the urine loss is associated with neither the stress nor the urge type, the incontinence is labeled "other." However, when the survey respondents were taken one step further into urodynamic testing, the type of incontinence has been classified into the various urodynamic types according to the pathophysiological abnormality.

Interestingly, when urodynamic testing is performed on women with UI, there is often a discord between subjective and objective findings [16–18]. Cundiff et al. evaluated 535 women over a 10-year period via detailed history and physical exam, urinary diary, and urodynamics. They found that by utilizing symptoms alone, a misdiagnosis would be made in 13% of women reporting only stress incontinence and 59% of women reporting only urge incontinence [19]. Some of this can likely be explained by the artificial nature of office urodynamics and other technical issues, but patient's poor understanding of the different types of UI and incomplete history taking may also be implicated.

The age of onset may be an important factor in the type of UI experienced. Kinchen et al. found the median age of American women reporting stress incontinence was 48 years, mixed incontinence was 55 years, and urge incontinence was 61 years [20]. Luber et al. evaluated 642 incontinent women and discovered that stress incontinence was more common in younger women aged 30–49 years (78%) versus those aged 50–89 years (57%). Urge incontinence predominates in the older population (67%) versus women under the age of 50 years (56%) [21].

According to Nygaard et al., the rate of urge incontinence tends to rise with age, while the rate of stress incontinence decreases somewhat in the oldest age groups, possibly due to lower activity levels [13] (Figure 2.1).

The MESA survey conducted by Diokno et al. [2] in Washtenaw County, Michigan, reported the prevalence of the types of clinical incontinence encountered among their respondents. The most common type reported by these women aged 60 years and older was the mixed stress and urge type (55.5%), followed by the stress type (26.7%), the urge (9.0%), and other types (8.8%).

A meta-analysis of published studies of UI epidemiology in the world suggested that stress incontinence is the most common form [22]. Stress incontinence accounted for almost half of the total worldwide prevalence of UI and mixed incontinence constituted 29% of the total prevalence. The analysis showed that urge incontinence was less common, consistent with the U.S. and European surveys.

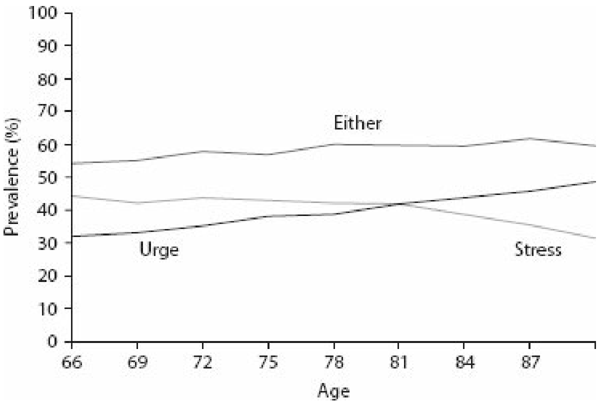

Figure 2.1 Prevalence of incontinence by age groups at baseline. Each age represents the midpoint of a three-year age range. Because of the small number of women above age 90, the graph ends with age range 86–88 years. "Urge" and "stress" refer to women who answered affirmatively to the urge and stress incontinence questions, respectively. "Either" refers to women who reported any incontinence (either urge or stress). (Data adapted from McGrother CW et al., *Br J Urol Int*, 93, 763, 2004.)

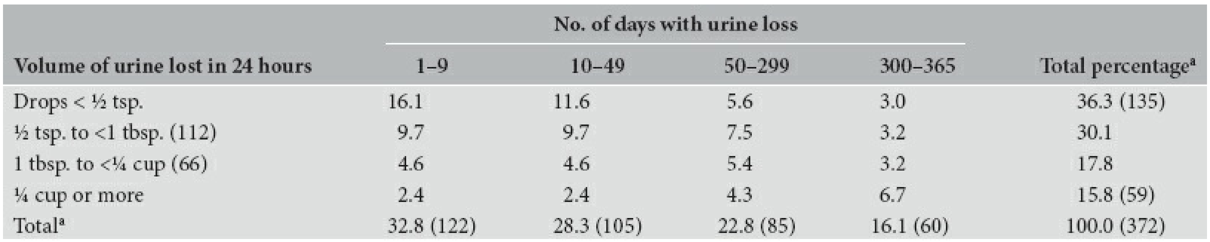
Table 2.2 Percentage of Severe Incontinence, as Judged by Volume and Frequency of Urine Loss, in 60-Year-Old Women



Volume of urine lost in 24 hours	No. of days with urine loss 1–9	10–49	50–299	300–365	Total percentage[a]
Drops < ½ tsp.	16.1	11.6	5.6	3.0	36.3 (135)
½ tsp. to <1 tbsp. (112)	9.7	9.7	7.5	3.2	30.1
1 tbsp. to <¼ cup (66)	4.6	4.6	5.4	3.2	17.8
¼ cup or more	2.4	2.4	4.3	6.7	15.8 (59)
Total[a]	32.8 (122)	28.3 (105)	22.8 (85)	16.1 (60)	100.0 (372)

Source: Diokno AC et al., *J Urol*, 136, 1022, 1986.

*Note:*Respondents with mild incontinence were those who reported low frequency (1–9 days/year) and/or small volume (<½ teaspoon/day for <300 days/year); those with severe incontinence were those who reported high frequency (≥300 days/year) and/or large volumes (>¼ cup/day on ≥50 days/year); those respondents with intermediate volume and/or frequency were considered to have moderate incontinence.

[a] Number of patients in parentheses.

Prevalence and Incidence of Severity of UI

In epidemiological studies, severity has been categorized by the frequency of incontinent episodes, by the volume of urine loss, or by the frequency of difficulty in controlling the flow of urine. The Diokno MESA study [2] reported the severity of UI among its 60-year-old respondents in terms of the number of days per year that urine loss was experienced and the volume of urine loss per day. As shown in Table 2.2, if severe or significant UI is considered to be the loss of at least a quarter cup of urine per day on 50 or more days/year, and frequency of incontinence is 300 or more days/year regardless of volume, then 20.4% of women respondents age 60 years and older at the time of the MESA survey had severe incontinence.

The patterns of change in the severity of UI in the MESA survey were also analyzed [10]. Based on the severity levels described in Table 2.2, continent respondents who became incontinent were most likely to develop a mild form of incontinence. About half of those who were classified originally as mildly incontinent remained so and very few became severely incontinent. Among those who reported moderate incontinence, most remained moderately incontinent or changed to mildly incontinent, with very few advancing to severe incontinence. Among women who were severely incontinent at baseline, most remained severely incontinent.

Kinchen et al. revealed that over 50% of incontinent respondents have urine loss at least once per week [20]. The severity of incontinence symptoms influences a woman's willingness to discuss the symptoms with a physician. Fewer than 20% of women report discussing incontinence with a physician within the past year when symptoms are mild. The proportion increases to 42% of women when symptoms are severe [23].

Prevalence of Voiding Frequency

The prevalence of voiding frequency is receiving greater attention as more and more studies are being conducted for conditions related to bladder dysfunction. For example, pharmacological interventions and behavioral techniques aimed at improving bladder function usually affect the frequency of voiding day and night. It is therefore imperative that a comparative standard is available on which to base any observations related to frequency of voiding prior to, during, and after an intervention.

The MESA study has established the distribution of voiding frequency among the elderly (60 years and older) living in a community, who are likely to be the subjects of pharmacological and behavioral interventions aimed at controlling abnormal voiding [2]. It appears that the normal daily frequency of urination in this age group is no more than eight times, as 88% of all our asymptomatic respondents reported that range. To be more specific, 47.3% of asymptomatic women reported that they voided six to eight times, 34.8% voided four or five times, and 5.5% voided one to three times daily. FitzGerald et al. reevaluated the definition of urinary frequency by evaluating 300 asymptomatic women aged 18–91 (median 40 years) who volunteered from a large metropolitan community. These women completed a 24-hour log of fluid intake and volumes voided. They found a median of eight voids in 24 hours with 95% of subjects recording less than 13 voids per 24 hours. Their conclusion was that using greater than or equal to eight voids per 24 hours as the definition of "frequency" may be inappropriate, suggesting that "frequency" may be greater than or equal to 13 voids in 24 hours [24]. Since the information came from a self-selected group of volunteers that reside in a large metropolitan area, their findings may not represent the true frequency of voiding in the general community.

In an investigation by the Bladder Diary Research Team, 161 asymptomatic women from 19 to 81 years of age were recruited at four independent research sites. Each subject completed a 3-day bladder diary to establish normative values based on age and 24-hour urine volumes. They found that there was a statistically significant increase in frequency with increased age and 24-hour volume. They also found a mean of 7.1 voids per 24 hours, with a range of 2–13, and that 95% of subjects recorded less than 10.4 voids per 24 hours [25]. The same group looked at 92 asymptomatic males from 20 to 84 years of age. They found a mean frequency of 6.6 with a range of 3–14 and 95% voiding less than 9.5 times per 24-hours [26]. While the numbers are slightly lower than those from the MESA study, they bolster their conclusion that utilizing eight voids as the definition of frequency may be incorrect and may need to be adjusted based on age and 24-hour urine volume.

In terms of nocturia—which was defined as the frequency of being awakened from sleep and getting up to void—93% of asymptomatic women voided no more than twice at night? In contrast, 25% of women with irritative symptoms and 24% of women with difficulty in emptying the bladder voided three or more times each night [2]. These data suggest that abnormal bladder function has a significant effect on the frequency of voiding. Incontinent women are voiding much more frequently than continent women. FitzGerald et al. [24] recorded nighttime voids in 44% of their population. While 8% voided greater than or equal to two times per night, 36% voided once during the night. The number of nighttime voids was dependent only on the patient age.

QUALITY OF LIFE

UI has a significant impact on a woman's quality of life. Fultz et al. examined 174 respondents who were moderately to extremely bothered by stress incontinence symptoms. Of these women, 54.4% reported that their symptoms had a moderate to extreme impact on physical activities and 42.7% perceived such impact on confidence, 38.6% on daily activities, and 36.5% on social activities [3]. The odds of moderate-to-extreme bother/burden decreased with age and increased with symptom severity.

The relative risk of admission to a nursing home is two times greater for incontinent women according to Thom et al. [27]. Over half of all female nursing home residents are reported to have "difficulty controlling urine," and over half need assistance in using the toilet [28].

PREVALENCE OF URODYNAMIC MEASURES AMONG CONTINENT AND INCONTINENT ELDERLY WOMEN

To establish the urodynamic characteristics of both continent and incontinent elderly women living in a community, a series of urodynamic tests were conducted on those MESA respondents who volunteered to undergo such tests [29,30]. This study provided information on the prevalence of the various parameters in the urodynamic tests that are of interest in the evaluation of incontinent patients but for which there are no well-established data from control subjects. The MESA survey data established the sensitivity and specificity of the various urodynamic tests, from which it was concluded that such tests—including uroflow, cystometrography, static urethral profilometry, and stress cystography—should be used, not to screen and diagnose UI but, rather, to confirm clinical manifestation. Recent studies confirmed the lack of concordance between clinical manifestations and urodynamic findings [16–18].

The MESA survey studied a random sample of noninstitutionalized ambulatory elderly women, both continent and incontinent; an initial clinical evaluation was followed by a series of urodynamic evaluations. A total of 258 self-reported continent and 198 self-reported incontinent women underwent the clinical evaluation comprising history taking, physical examination (including pelvic examination), and urinalysis. From these groups, 67 continent and 100 incontinent women underwent urodynamic testing including an initial noninstrumented uroflow test, followed by catheterized postvoid volume measurements, followed by filling cystometry, static and dynamic urethral profilometry, provocative stress test, and lateral stress resting and straining cystogram.

UROFLOWMETRY

The uroflow measures of peak flow rate (PFR) and average flow rate (AFR) were analyzed according to the voided volume at increments of 100 mL. When volume was controlled, the mean PFR and AFR did not differ significantly between respondents who were continent and those who were incontinent. The flow rates did not differ between women with competent sphincters and those with urethral incompetence. The continuity of the urinary stream was not associated with continence status or with the clinical type of incontinence (i.e., urge, stress, etc.).

Postvoid Residual Volume

A postvoid residual volume of 0–50 mL was found in 78.1% of continent and 86.5% of incontinent women, 9.7% and 8.4% had residuals of 51–100 mL, 2.4% and 1.6% had residuals of 101–150 mL, and 9.7% and 3.5% had residuals of 151 mL or more, respectively. There was no statistical difference between continent and incontinent women with regard to prevalence of a residual urine volume greater than 50 mL. These data give rise to questions regarding the postvoid residual volume in relation to the diagnosis of overflow incontinence: the determining factor for overflow incontinence may be the same factor as for urge and/or stress incontinence, and the abnormal postvoid residual volume may be coincidental or a contributory factor rather than a primary reason for the incontinence.

Bladder Capacity

Among the women volunteers, 79% of continent volunteers and 64% of incontinent volunteers had a bladder capacity of 300 mL or more; however, this difference in bladder volume between continent and incontinent subjects was not significant. The mean cystometric bladder capacities among 60- to 64-year-old continent and incontinent subjects were 381.8 and 442.7 mL, respectively; for 65- to 69-year-old subjects, they were 421.6 and 370.0 mL; for those aged 70–74 years, they were 410.3 and 414.2 mL; for those aged 75–79 years, they were 350.3 and 426.8 mL; and for those aged 80 years old or more, they were 318.3 and 408.3 mL, respectively. These results refute the notion that the bladder capacity of the elderly is smaller than normal, if we consider a bladder capacity of 300 mL or more to be normal.

Uninhibited Detrusor Contraction

The diagnosis of uninhibited detrusor contraction was based on the definition by the International Continence Society. The overall prevalence of uninhibited detrusor contraction in women was 7.9%; the prevalence of uninhibited detrusor contraction among continent respondents was 4.9%, whereas for incontinent subjects, it was 12.2%. The difference between the two prevalence rates was not significant. However, comparison of the bladder capacity between female respondents showed that the capacity in women with uninhibited detrusor contraction was 364 mL, whereas in those without uninhibited contractions, it was 404 mL; the difference was statistically significant at $p < 0.05$. This may explain the increased frequency, urgency, and smaller voided volumes of patients with detrusor overactivity.

Static and Dynamic Urethral Pressure Profilometry

The mean functional urethral length (FUL) did not change significantly as the age of the subjects increased, but the values of the maximum urethral pressure (MUP) and the maximum closure pressure (MCP) showed a significant progressive reduction as age increased ($p = 0.002$ and $p = 0.0003$, respectively). This progressive reduction of MUP and MCP reinforces the belief that elderly women are more predisposed to stress urine loss.

The parameters of urethral pressure profilometry for supine subjects did not show any significant difference between continence and incontinence. However, for standing subjects, significant differences were observed between continent and incontinent groups with respect to MUP, which was significantly ($p = 0.0025$) lower in the incontinent compared with the continent group. Likewise, the MCP and the FUL were significantly reduced in standing but not in supine incontinent subjects when compared with the continent group.

The results of dynamic profilometry were reported as either positive (zero or positive reading), corresponding to incontinence, or negative (corresponding to continence). There was no significant difference between incontinent and continent subjects in the supine position, but there was between the groups in the standing position. Despite this significant difference, there was a great deal of overlap between the results for the continent and incontinent groups, invalidating a diagnosis based on this test alone. However, these findings lead credence to weakened pelvic floor muscle support for incontinent woman in the standing position.

Lateral Stress Cystography

Comparison between continent and incontinent subjects and between those with different types of incontinence, with regard to urethral axis, posterior urethrovesical angle (PUV), and distance of urethrovesical junction to the urogenital diaphragm (UGD), showed that incontinent respondents had a significantly (*p* = 0.001) wider PUV angle than did continent respondents; however, no significant difference was observed between stress and nonstress types of incontinence. There was no difference in the urethral axis and the position of the bladder neck in relation to the UGD between the groups according to continence status or clinical type of incontinence. There was a significantly greater mean PUV angle among incontinent subjects with an incompetent sphincter than among continent subjects with a competent sphincter (*p* = 0.004); however, neither the measurements of the urethral axis nor the location of the UGD differed between these two groups.

PROVOCATIVE STRESS TEST

A provocative cough stress test was found to be significantly correlated to continence and incontinence status and, more specifically, to the stress type of urine loss with or without urge loss (*p* = 0.0005). The result of the stress cystogram, when correlated with the stress test, showed a strong association (*p* = 0.009). A urethral axis of 30° or more is more likely to give rise to a positive stress test than is an axis less than 30°. The stress test can be performed as part of the initial office evaluation and does not require special equipment: there is no morbidity, it is inexpensive and (more importantly) it has extremely high specificity; it should be a part of everyone's initial evaluation. However, a negative test in someone who is experiencing UI does not rule out its existence, as sensitivity of the test often is only 40%.

Medical Correlates of UI

Several medical conditions have been associated with UI in women. Difficulties with physical mobility, lower urinary tract symptoms, bowel problems, and diabetes are more common in women with incontinence. Other factors associated with UI include a family history of incontinence, vaginal childbirth, and estrogen hormone use. Many of these associations were identified through the MESA survey [31].

Patients who used wheelchairs or walking aids had a diagnosis of arthritis or who had fallen in the past year were defined as having mobility difficulties in the MESA survey. In women with mobility problems, urge incontinence was more common than any other type.

Regarding urinary tract and bowel problems, women with UI had a history of more urinary tract infections, dysuria, hesitancy, urgency, and slow stream than continent women. In addition, those who had more fecal incontinence or constipation had a higher rate of UI. Women with stress incontinence were the least likely of all urinary incontinent patients to lose control of their bowels.

Diabetes effects more than 12% of adults older than 40 and the prevalence increases to 19% of adults older than 60 [32]. Diabetic women have a 30%–70% increased risk of UI [31,33,34]. The risk of urge incontinence was increased about 50% among women with diabetes, while they had no increased risk of stress UI [6]. The mechanism for the incontinence is unclear. Possibilities include hyperglycemia [35] and microvascular complications causing altered innervation to the bladder [36]. Most prior studies on diabetic people with incontinence were conducted on elderly patients with type 1 diabetes who may have had other neurological or urological reasons for their incontinence. A recent cross-sectional analysis of a younger cohort of type 1 diabetics from the Epidemiology of Diabetes Intervention and Complication study demonstrated twofold greater odds of urge incontinence and 50% greater odds of stress incontinence compared to a matched cohort from the National Health and Nutrition Examination Survey [37]. Furthermore, UI was found to be more prevalent than neuropathy, retinopathy, or nephropathy. Data from the prospective, observational Nurses' Health Study cohort of more than 70,000 married registered nurses found type 2 diabetes to be a strong independent risk factor for UI [38,39]. In addition, the study found that the risk of incontinence increases with the duration of type 2 diabetes allowing the investigators to conclude that simply delaying the onset of diabetes could have important public health implications. Data from the Diabetes Prevention Program in prediabetic women showed that total weekly incontinence at three years was lowest in women randomized to the intensive lifestyle (34%) compared with metformin (48%) or placebo (46%) [40]. Weight loss accounted for the largest impact on incontinence in this study and underscores the difficulty the role of many confounding factors such as parity, stroke, diabetes, age, and body weight play in drawing causative conclusions. Further research is needed to define the role diabetes plays in UI and the impact intervention may have on decreasing its incidence. Females with incontinence more often reported a parent or sibling with UI than continent women. It was also noted that UI patients had a higher rate of personal UI during adolescence versus continent patients.

There is an increased risk of later UI after a vaginal delivery, even after the first delivery [41]. An increased risk of surgery for the stress UI is also seen after a vaginal delivery [42]. During pregnancy, there is an increased prevalence of incontinence, especially in the third trimester, which usually resolves shortly after delivery [43]. Possible etiologies are hormonal changes during pregnancy, damage to the pelvic muscles, and nerve injury during labor and delivery [44]. It is difficult to identify the specific parturition risk factors, as there are many potential, interrelated factors that occur during a single pregnancy and delivery. Most observational studies have demonstrated that cesarean sections are protective against incontinence versus vaginal deliveries [45,46]. The EPINCONT study of more than 15,000 Norwegian women demonstrated overall incontinence rates of 10% of nulliparous, 16% of cesarean section, and 21% in vaginal delivery only women [47]. However, the protective role of cesarean section diminished when adjusted with increasing age. An interesting study of identical twins at the annual Twins Day Festival in Twinsburg, Ohio, found that vaginal delivery more than doubled the report of stress UI compared to cesarean section [48]. In 2007, a systematic review of the literature by Press found that cesarean section reduced the risk of postpartum stress UI from 16% to 9.8% in six cross-sectional studies and from 22% to 10% in 12 cohort studies [49]. From these data, they calculated that between 10 and 15 cesarean sections would need to be performed to prevent one woman from developing SUI. Less is known about the cesarean section timing (before labor, in labor but without pushing, or in labor and pushing) and its effect on incontinence. A study of Israeli women 1 year after their first delivery found similar stress UI rates in women undergoing vaginal deliveries (10%) and cesarean for obstructed labor (12%) compared to planned cesareans (3%) [50].

Historically, estrogen, either vaginal or oral, was thought to improve incontinence episodes in postmenopausal women. The trigone and urethra are covered by nonkeratinized squamous epithelium, and these tissues contain estrogen receptors [51] and respond to estrogen [52]. There have been many uncontrolled trials demonstrating subjective improvement in incontinence, while a few randomized controlled trials showed no significant difference between control and treatment groups [53,54]. The Heart Estrogen Replacement Study found intriguing UI outcomes when comparing a regimen of conjugated estrogen and medroxyprogesterone acetate with placebo [55]. Incontinence improved in 26% of women given placebo compared to 21% assigned to combined estrogen/progestin, whereas 27% worsened in the placebo group compared to 39% receiving hormonal replacement. They concluded the effect of estrogen might be cancelled by the progesterone, as progestin has been shown to decrease intraurethral closing pressure.

In the United States, approximately 31% of adults are obese and 33% are overweight, with the most rapid increase among those in the younger (18–29 years) age range [56]. Numerous epidemiological studies have demonstrated an association between obesity and stress UI. Women with a median body mass index (BMI) of 28.2 had a higher incidence of UI than those with a BMI of 25.5 (normal range) [57]. Odds ratios as high as 1.6 per 5-unit increase in BMI have been demonstrated [56]. The additional weight is believed to result in higher pressures on the bladder and causes an increase in urethral hypermobility. In a urodynamic evaluation study of subjects from the Program to Reduce Incontinence by Diet and Exercise trial, BMI had a stronger association with intra-abdominal pressure than with intravesical pressure [58]. The authors suggested that increasing weight might push women closer to their threshold for UI episodes even if their intrinsic continence mechanisms are comparable. Randomized nonsurgical weight reduction studies suggest losing 5% or more of body weight can lower UI episodes by as much as 70% [56]. In fact, reduction in UI frequency has been suggested to be a powerful motivator for lifestyle modification. UI following gastric bypass surgery has resulted in similar reductions, which correlate significantly with decrease in BMI [56,59]. The BACH survey reported that the waist circumference at baseline and increasing waist circumference over 5-year follow-up were the most robust predictors of UI incidence. They also reported that for incontinent at baseline, persistence of UI was associated with depression symptoms and alcohol consumption [14]. Nygaard et al. also reported the association between depression and incontinence in middle-aged women [60].

Patterns of Reporting of UI

According to a nationwide, two-staged, cross-sectional postal survey conducted by the NFO World group [61], 41.6% of incontinent women believed their incontinence was a natural part of growing older and 47.0% accepted it as a part of their life.

Approximately 86% of women reported being bothered by symptoms of UI, with 25.6% reported being moderately bothered, 14.5% very bothered, and 8.5% extremely bothered. Only 44.9% of these incontinent women had ever talked to a physician about it. Those who were more bothered by their symptoms were more likely to have talked to a physician (not bothered, 25.2%; slightly bothered, 37.1%; moderately to extremely bothered, 56.5%). Older women were also more likely to talk to a physician than younger women (53.5% vs. 39.8%).

Of the incontinent women who spoke with a physician, 2.9% first talked with a family practitioner, 35.1% with an obstetrician–gynecologist, 10.9% with an internist, and 4.4% with an urologist. Of all women who initially spoke with an internist or family practitioner, 19.0% were later referred to a urologist and 17.3% to a gynecologist.

Coping Strategies to Control UI

Patient self-care practices were also evaluated by the NFO World group [61]. Of all the women surveyed (bothered and nonbothered by UI), 42.1% currently used panty liners, 33.5% used the toilet frequently even when they did not have an urge to urinate, and 29.5% sought out a toilet immediately upon arriving at an unfamiliar location. Of the incontinent women, 23.3% limited their fluid intake and pelvic floor muscle exercises were performed by 19.9% of all UI women and by 20.3% of women with stress symptoms only. Only 6.3% of all the women are currently being treated with prescription medications and 2.1% have had surgery for their UI.

CONTINENT SURGERY AND ITS OUTCOMES

An estimated 126,000 continence surgeries are performed annually in the United States [62]. A review of the literature demonstrates that the median proportion of women cured or improved by surgery at 1–2 years was 78% for anterior repair, 86% for retropubic suspension, and 91% for sling procedures [63]. However, the NFO World group panel evaluated the prevalence and outcomes of continence surgery in community-dwelling women via a postal survey [64]. Four percent of community-dwelling women and 8% of women 60 years or older had a history of continence surgery. The initial satisfaction of surgery was high but then decreased as time progressed. Of those who had surgery within the past 3 years, 64% were currently satisfied, where only 41% were satisfied if their surgery was 3–5 years ago. Seventy-three percent of the women who had surgery reported incontinence in the preceding month, 58% in the preceding week, and 53% who used pads. Of those with recurrent UI, 83% complained of stress incontinence. One-third of the women had their surgery within the last 5 years.

PREVALENCE OF PELVIC ORGAN PROLAPSE

Pelvic organ prolapse is often a concurrent problem with UI. The prevalence of pelvic prolapse was evaluated by Hendrix et al. in 2002 by analyzing women who enrolled in the Women's Health Initiative Hormone Replacement Therapy Clinical Trial [65]. In women with a uterus, the rate of uterine prolapse was found to be 14.2%, cystocele was 34.3%, and rectocele was 18.6%. For women who had a hysterectomy, the rate of a cystocele was 32.9% and a rectocele was 18.3%. Hispanic women had the highest risk for uterine prolapse and African-Americans had the lowest risk. Finally, parity and obesity were strongly associated with an increased risk of uterine prolapse, cystocele, and rectocele. Nygaard detected no difference in prevalence by racial/ethnic group regarding pelvic floor disorders. The prevalence of women experiencing pelvic organ prolapse was 2.9% [66].

ECONOMIC BURDEN OF UI

The direct and indirect financial impact of UI on our health-care system is significant. Hu et al.

estimated the total cost of UI was $19.5 billion (year 2000 dollars) [67]: $14.2 billion was due to community residents and $5.3 billion due to institutional residents. The direct costs for community residents, which included absorbent products, laundry, treatment, and consequences (UTIs, etc.), were $13.66 billion. Indirect costs, which involved lost productivity secondary to missing work, for community residents was estimated to be $553 million, with a $393 million loss for women and $159 million loss for men. For the institutionalized individual, the direct cost is $5.32 billion.

PREVENTION OF UI IN THE COMMUNITY

One of the ultimate goals of any epidemiological study is to improve population health through prevention based on lessons learned. The MESA epidemiological project in the first 20 years has contributed to the knowledge on prevalence, incidence, remission rates, and correlates of UI. The team members also established the efficacy and safety of behavioral modification program (BMP) in managing geriatric incontinence. It became clear that the next step (armed with this information) is to apply the BMP not only for treatment but also for prevention of UI.

Diokno et al. then embarked on a randomized controlled study using BMP taught to groups of women who were incontinent or having no more than five UI episodes in the last 365 days based on the MESA questionnaire. A 2-hour class presentation of BMP was given to the intervention group of 164, whereas the control group of 195 did not receive any instruction. At the end of 12 months, the primary outcome measure was the number of days UI occurred based on the MESA questionnaire. Secondary measures included voiding frequency and the intervoid interval based on a 3-day voiding diary. At 12 months, the treated group was statistically significantly better than the control group in continence status ($p = 0.01$) (Figure 2.2), pelvic muscle strength (Figure 2.3) (pressure score $p = 0.0003$ and displacement score $p < 0.0001$), improved voiding frequency ($p < 0.0001$), and intervoid interval ($p < 0.0001$) [68].

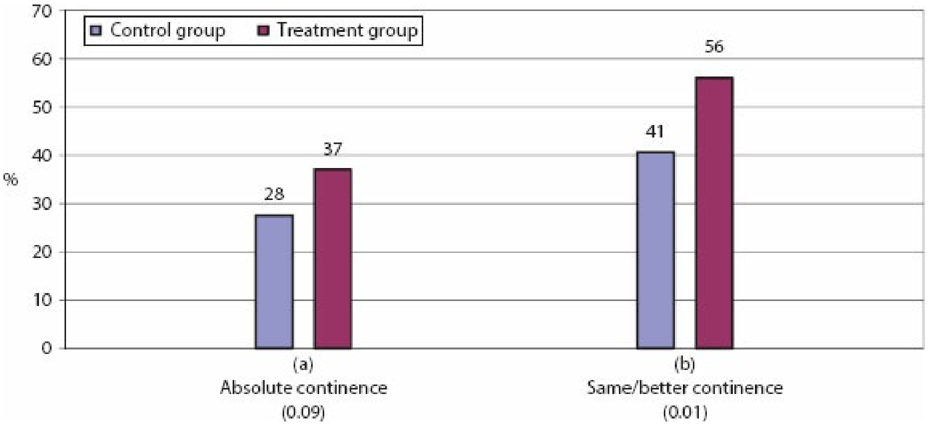


Figure 2.2 Continence in control and treatment groups at 12-month exit. At baseline, two groups reported identical 39% absolute continence and 0 urinary incontinence (UI) days with 61% of participants reporting 1–5 UI episodes in a year. (a) Absolute continence criterion: Percentage of participants that remained or became absolute continent at exit. (b) same (0 or 1–5 UI days) or improved continence criterion: Percentage of participants with the same or improved continence level at exit. The bars represent percent of participants. Values in parentheses represent control vs. treatment *p*-values. (From Diokno AC et al., *J Urol*, 171, 1165, 2004. With permission.)

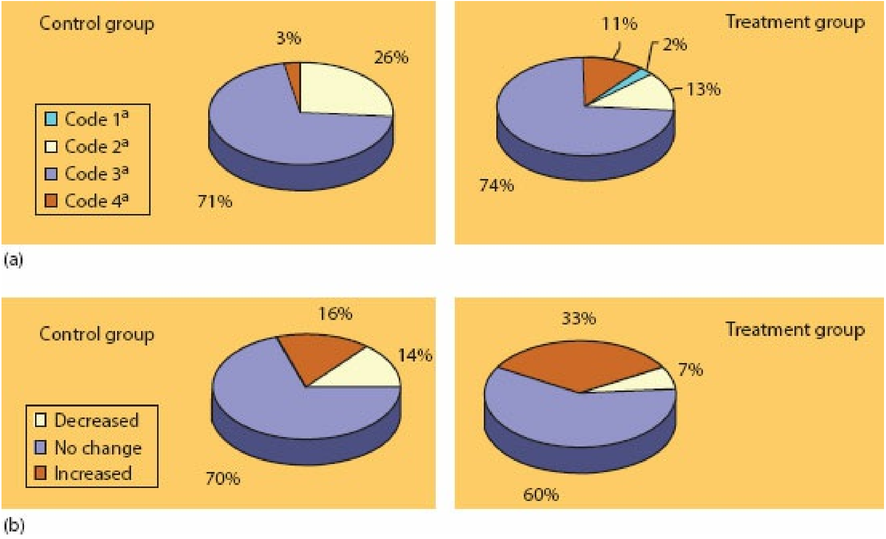

Figure 2.3 Pelvic floor muscle strength scores in treatment and control groups. (a) Portion at each strength level. At 12-month exit, treatment group had higher digital pressure scores than controls, suggesting stronger pelvic floor muscles (*p*-value = 0.0003). (b) Changes in pressure scores at 12-month exit vs. baseline (p-value = 0.0008). More treatment than control participants had improved score at exit compared with baseline. [a]Pressure codes: 1, no pressure; 2, flick and incomplete circumferential pressure points; 3, full but loose circumferential pressure to being snug; 4, circumferential compression to overriding of fingers. (From Diokno AC et al., *J Urol*, 171, 1165, 2004. With permission.)

CONCLUSION

UI is a prevalent condition that can affect women of all ages. The incidence is especially high in the elderly population. UI is associated with many medical conditions. Urodynamic testing can help explain the mechanism of UI. Many women with UI think that it is a part of the normal aging process and do not talk to their physicians about this condition. Despite the advancement in medical and surgical treatment of UI, many women's satisfaction rates with treatment are not as high as some physicians perceive it. Recent randomized controlled trial of BMP for preventing UI in older women demonstrated feasibility and efficacy in improving continence status, pelvic muscle strength, and voiding control for as long as a year after treatment.

3 Epidemiology: South America

Paulo C.R. Palma, Miriam Dambros, Fábio Lorenzetti, and Fabio Thadeu Ferreira

INTRODUCTION

Worldwide, urinary incontinence (UI) is a common problem that can affect 17%–45% of adult women. The high cost in terms of personal well-being [1] and financial expenditure for both individuals and society [2,3] makes this syndrome a major public health concern. The most prevalent type is stress incontinence, being responsible for 48% of all cases. Next to stress incontinence, urge incontinence is the second most prevalent cause of incontinence (8%–17%) [4,5]. Mainly due to shame, taboo, and unawareness of treatment possibilities, only a minority of women suffering from incontinence seek professional help. In daily practice, patients usually seek help only when urine loss leads to significant mental, physical, and social problems, as well as discomfort, often after many years of suffering. The prevalence of UI is the probability of being incontinent within a defined population at a defined point in time, estimated as the proportion of incontinent respondents identified in a cross-sectional survey [6]. The World Health Organization (WHO) defines health not only as the absence of disease but also as a "state of physical, emotional and social well being" [7]. According to the old International Continence Society definition, UI causes hygienic and social problems [8], and results in quality-of-life (QoL) impairment, depression, and sexual problems [9]. UI has a significant impact on the QoL of 20% of women [10]. Epidemiological studies dealing with UI are sparse and methodologies varied. In South America, very little research has been done on this subject, and, as a consequence, there is conflicting information, especially in respect to South American prevalence rates.

ETIOLOGICAL FACTORS

It is generally believed that the main etiological factor leading to UI is one or more vaginal deliveries, with an increase in risk with greater parity [11]. Possible etiologies for UI include distension or disruption of the muscles, ligaments, and nerves responsible for bladder control that occurs during vaginal delivery [12]. Other authors, however, have found that the occurrence of UI during pregnancy in nulliparous women has a stronger association with persistent incontinence after delivery than with parity [13]. This would suggest a more significant effect from pregnancy itself than the process of vaginal delivery. Women who are not exposed to vaginal childbirth by having all their babies by cesarean section (CS) offer the opportunity to check the relative relevance of pregnancy itself, as compared with vaginal delivery, as a risk factor for UI.

Tamanini et al. evaluated women to identify prevalence, associated factors, and risk factors for UI as well as the impact on the QoL in women seeking for cancer prevention screening. The method of choice was cross-sectional analysis of 646 women who sought cancer prevention screening in Oncologic Hospital in October 2005. The prevalence, severity, and impact of UI on the QoL were assessed by means of International Consultation on Incontinence Questionnaire (ICIQ-SF) [14]. Mean age was 37.7 years (ranging from 12 to 79). General UI prevalence rate reached was 34.8%. The ICIQ-SF final score from the whole population sample was 3.1 (ranging from 0 to 21) increasing to 8.9 in the incontinent group. Age, literacy, diabetes, and hypertension were associated with UI and were considered and identified as risk factors along with frequency of pregnancies (Table 3.1). Family wages per month (<4), neurological diseases, and parity and its mode (vaginal delivery or CS) were not considered risk factors in this study. Elderly women (older than 60 years) had three times the odds of UI compared to those younger than 40 years. Women with hypertension had 1.7 the odds of UI compared to those with no hypertension. UI was highly prevalent among this sample of population of our area. Furthermore, UI caused moderate impairment on the QoL (Table 3.2) of women who sought cancer screening. UI should be considered a major public health problem in the studied area. Risk factor identified were age (Figure 3.1), literacy, diabetes, hyperlipidemia, absence of physical exercises, intense manual labor, frequent urinary infections, hypertension, and frequency of pregnancy and vaginal delivery with episiotomy [15]. Overall, elderly women with hypertension are at a high risk of UI [16].

Latin America has one of the highest rates of CS in the world, with a tendency toward a further increase. Recent estimates indicate that the incidence of CS varies between 16.8% and 40% in most Latin American countries [17] and that this rate is higher in private hospitals than in public hospitals. In addition, the incidence of CS is greater in those Latin American countries with a higher per capita gross domestic product. Although strategies to reduce CS rates have been proposed, very few have been assessed through randomized controlled trials.

15, 2014.)

URINARY INCONTINENCE, QUALITY OF LIFE, AND SEXUAL FUNCTION

Recently, many studies have measured the QoL in incontinent patients, using a number of different self-administered condition-specific and generic QoL questionnaires. The impact of UI on patients' lives does not appear to be directly related to the volume of urine loss, although it does appear to be related to the overall burden of symptoms [18].

An open prospective study was carried out at our institution, enrolling patients with UI. The aim was to look at the relationship of UI and QoL issues, particularly with respect to altered sexual function. The study population consisted of 30 women aged between 31 and 51 years (mean 43 years). The duration of symptoms ranged from 12 to 53 months. All the patients were multiparous and 60% of women had incomplete elementary education. Two sexual function questionnaires were completed by respondents. The female sexual function index identifies problems related to sexual response and possible dysfunctions, as well as issues related to libido, excitement, lubrication, orgasm, pleasure, and pain. The Impact of Urinary Incontinence on the Sexual Response/RJ questionnaire [19,20] identifies the effects of UI on sexual function, social problems, and self-esteem. It also evaluates adaptive changes to cope with urinary symptoms, and sexual behavior before and after the onset of UI.

Of the 30 women participating in the study, 26 (86%) were married and all had only one partner, 19 (63%) were catholic, and 18 (60%) had incomplete elementary education. Concerning the effects of UI on daily life (Table 3.3), the major problems identified were the bad smell caused by urinary leakage, the need to use pads for 13 patients (43%), and the involuntary loss and wetness for 12 (40%). In addition to the results in Table 3.3, the study also showed that there were significant effects of UI on self-esteem, 11 patients (37%) having the feeling of being less valued, with 17 (57%) women having a worsening of their sexual lives as a result of their urinary symptoms. Twenty-three patients (76%) related that they had urinary loss during sexual intercourse. Among these, 17 (74%) claimed it as a negative influence on their sexual life. Of the 23 patients, 6 (26%) did not complain, 2 (9%) considered it a mild interference, 4 (17%) evaluated it as moderate, and 11 (48%) indicated it as a severe interference. Regarding the frequency of sexual intercourse before and after the onset of incontinence, 17 patients (57%) expressed altering patterns. Sexual activity changed from weekly to monthly in seven patients (41%), from daily to weekly in five (29%), from daily to monthly in three (18%), from monthly to annual in one (6%), and from weekly to no relationship in one (6%). Differences in sexual function before and after the onset of incontinence were established. Ten variables related to sexuality were studied: desire, excitement, vaginal lubrication, general caresses, genital caresses, oral sex in the partner and in the patient, vaginal penetration, anal penetration, and orgasm. Six variables were significantly different following the onset of urinary leakage, with a worsening of sexual desire, genital caresses and general caresses, vaginal penetration, anal penetration, and orgasm. Abdo and colleagues studied the sexual lives of 1502 healthy Brazilian women and concluded that in 34.6% the greatest complaint was a lack of desire and in 29.3% was orgasmic dysfunction [21]. These results demonstrated a reasonable degree of sexual dysfunction among the general Brazilian population although this appears to be greater in the presence of UI.

Table 3.3 Most Frequent Problems Identified in Urinary Incontinence

Problem	**Frequency (%)**
Bad smell and use of tampon	13 (43)
Involuntary loss and wetness	12 (40)
Surgery indication	2 (07)
Stress incontinence	1 (03)
Urinary frequency	1 (03)
Urine loss in the presence of the husband	1 (03)

PREVALENCE OF CLIMACTERIC, UROGENITAL, AND SEXUAL SYMPTOMS IN A POPULATION OF BRAZILIAN WOMEN

A cross-sectional, descriptive, population-based study [22] was also carried out at the State University of Campinas on 456 women aged 45–60 years, living in Campinas, SP, Brazil, in 1997. Data were collected via home interviews, using structured validated. The results showed that climacteric symptoms in the population were highly prevalent and similar to those described in developed Western countries. Figure 3.2 shows the most prevalent symptoms identified. Hot flushes, sweating, and insomnia as expected were significantly more prevalent in peri- and postmenopausal women. The severity of vasomotor and psychological symptoms did not vary according to the menopause phase. Decreased libido was the most frequent sexual complaint. It was observed that some climacteric complaints were interrelated.

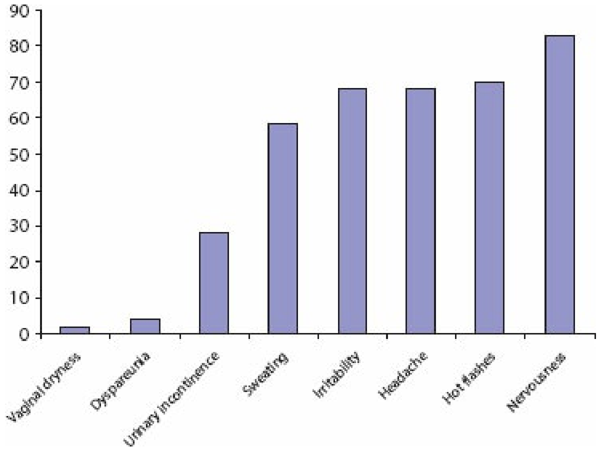

Figure 3.2 The most climacteric and urogenital prevalent symptoms found in the study of Pedro et al. [22].

PREVALENCE OF STRESS URINARY INCONTINENCE AND ITS ASSOCIATED FACTORS IN PERIMENOPAUSAL WOMEN

A descriptive, exploratory, population-based study with secondary analysis of a population-based household survey on the perimenopause and menopause was conducted among women living in a Brazilian city [23]. Through a sampling process, 456 women between 45 and 60 years old were selected. Thirty-five percent of the interviews complained of stress urinary incontinence (SUI). None of the sociodemographic factors studied was associated with the risk of SUI (Table 3.4).

In addition, parity did not significantly alter SUI risk. Other factors, such as previous gynecological surgeries, body mass index, smoking habits, menopausal status, and hormone replacement therapy, were not associated with the prevalence of SUI. There were no racial variations in the prevalence of SUI. In the international literature, most prevalence studies are conducted among Caucasian women, and only few studies have assessed racial differences in the prevalence of UI. In the few studies that have included other racial groups, a significantly larger percentage of Caucasian women appear to report UI compared to African–American or Hispanic females [24]. Urodynamic diagnosis showed that SUI was more frequent in Caucasian women compared to African-Americans. However, more research with regard to racial differences in the prevalence of UI is necessary to make significant conclusions regarding interracial differences in incontinence.

URINARY INCONTINENCE AMONG ELDERLY PEOPLE IN THE MUNICIPALITY OF SÃO PAULO, BRAZIL

Over the period from 1980 to 2025, the population aged 60 years and over in Latin America and the Caribbean is expected to at least double in size and, in more than half of these countries, to triple in size, before reaching the year 2025 [25]. This rapid and accentuated aging of the population will have a significant impact on social, economic, and health demands. Prominent among the health demands will be those relating to chronic diseases and their incapacitating sequelae and other complaints such as UI, which are all included among the so-called giants of geriatrics, given their negative consequences on QOL among elderly people [26].

Table 3.5 Distribution of Elderly People according to the Presence of Urinary Incontinence, Sociodemographic Variables, Health Status, and Functional Status

60–74 years		75 years and over

Doing instrumental ADLs[a]	18.4	81.6	35.7	64.3

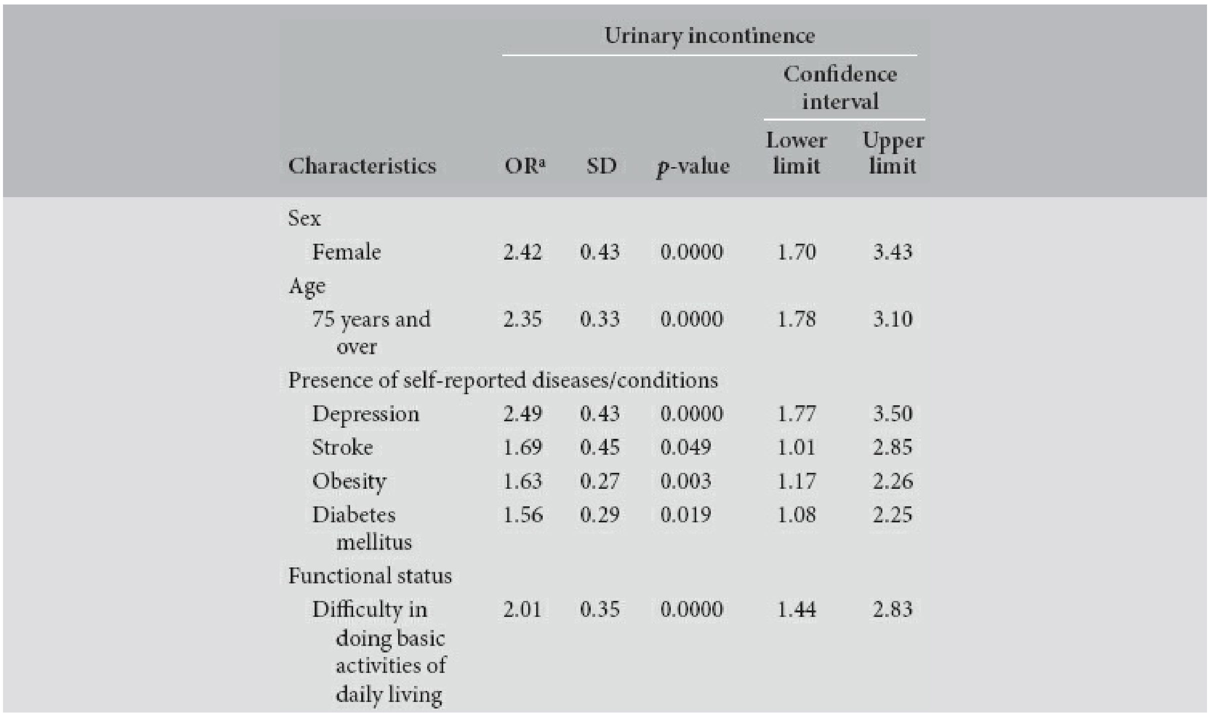
Note:Municipality of São Paulo, 2000.

[a] ADLs, activities of daily living; COPD, chronic obstructive pulmonary disease.

The Pan-American Health Organization and WHO [27] coordinated a multicenter study named Health, Well-being and Aging (SABE study) in elderly people living (over 60 years old) in seven countries of Latin America and the Caribbean. In Brazil, the study population carried out in São Paulo in the year 2000. The total Brazilian sample was 2143 people. The data were collected simultaneously, by means of home interviews, using a standardized instrument consisting of 11 thematic sections: personal data, cognitive assessment, heath status, functional status, medications, use of and access to services, family and social support networks, work history and sources of income characteristics of the home, and flexibility and mobility tests (Table 3.5).

The prevalence of self-reported UI was 11.8% among men and 26.2% for women. It was verified that among those reporting UI, 37% also reported stroke and 34% depression (Table 3.6). It was found that the greater the dependence that the elderly people presented, the greater the prevalence of UI was. The associated factors found were depression (odds – ratio = 2.49), being a female (2.42), advanced age (2.35), and important functional limitation (2.01). UI is a highly prevalent symptom among the elderly population of the municipality of São Paulo, especially among women. The adoption of preventive measures can reduce the negative effects of the UI.

Table 3.6 Final Model from Univariate and Multivariate Analysis for the Presence of Urinary Incontinence, according to Sociodemographic, Clinical, and Functional Characteristics of the Elderly People in the Municipality of São Paulo, Brazil, 2000



Characteristics	Urinary incontinence OR[a]	SD	p-value	Confidence interval Lower limit	Upper limit
Sex					
Female	2.42	0.43	0.0000	1.70	3.43
Age					
75 years and over	2.35	0.33	0.0000	1.78	3.10
Presence of self-reported diseases/conditions					
Depression	2.49	0.43	0.0000	1.77	3.50
Stroke	1.69	0.45	0.049	1.01	2.85
Obesity	1.63	0.27	0.003	1.17	2.26
Diabetes mellitus	1.56	0.29	0.019	1.08	2.25
Functional status					
Difficulty in doing basic activities of daily living	2.01	0.35	0.0000	1.44	2.83

[a] Adjusted OR (95% confidence interval) = odds ratio (95% confidence interval) adjusted using the logistic regression method, one by one for all variables and in the final model only for the significant variables.

CONCLUSION

UI is a highly prevalent condition in South America, as it is in many other parts of the world. Very few studies have concentrated on South American populations alone but those that have show a significant impact of UI on the QoL of sufferers.

INTRODUCTION

Urinary incontinence (UI), overactive bladder (OAB), and other lower urinary tract symptoms (LUTS) are highly prevalent conditions with a profound influence on well-being and quality of life as well as being of immense economic importance for the health service [1–4]. Millions of women throughout the world are afflicted [2,3], and there has been a growing interest in these symptoms in recent years as a consequence of the increased awareness of the human and social implications for the individual sufferer. Population studies have demonstrated that UI is more common in women than men and that approximately 10% of all women suffer from UI [2,3]. Prevalence figures increase with increasing age, and in women aged ≥70 years, more than 20% of the female population are affected. Inappropriate leakage of urine is perceived by many women but is not always reported to the doctor. However, an increasing awareness of the problem has in recent years attracted more patients to seek advice. In elderly women, UI may lead to possible rejection on the part of a relative and may be an important factor in the decision whether or not to institutionalize an elderly person. UI and other LUTS not only cause considerable personal suffering for the individual afflicted but are also of immense economic importance for the health service [4]. The annual cost of UI in Sweden, for example, has been reported to account for approximately 2% of the total health-care budget [1].

UI

This chapter describes the results of epidemiological studies performed in Europe. The reported prevalence of UI among women varies widely in different studies due to the use of different definitions, the heterogenicity of different study populations, and population sampling procedures. In addition, different definitions of UI have been applied. UI has been defined in the joint report from the International Urogynecological Association/International Continence Society as any involuntary leakage of urine [5]. However, some authors have chosen to restrict prevalence figures according to the frequency of involuntary urinary leakage—for example, based only on daily, weekly, monthly, or annual urinary leakage. Thus, for the reasons given earlier, it is difficult to compare the results of different population studies. However, when reviewing the literature, there is considerable evidence to support the theory that the prevalence of UI in women increases with age, but there are divergent opinions regarding the pattern of this increase [3,6–34].

In a review [3] of population studies from numerous countries, the prevalence of UI ranged from approximately 5% to 70%, with most studies reporting a prevalence of any UI in the range of 25%–45%. For daily incontinence, prevalence estimates typically range between 5% and 15% for middle-aged and older women.

Thomas et al. [6] investigated the prevalence of UI in two London boroughs by a postal survey (Figure 4.1a). The reported prevalence of UI increased from 5.1% in girls aged 5–14 years to 16.2% in 85-year-old women. There was, however, little or no change in prevalence rates up to 35 years of age. The prevalence rates then increased to approximately 10% in the 35–44 years age group. There was no significant increase at the time of the menopause, but a further increase to approximately 16% occurred in women ≥75 years. On the other hand, Iosif et al. [7] and Jolleys [14] (Figure 4.1b) reported a maximum prevalence of UI at the time of the menopause. Hannestad et al. [27], in a large Norwegian study, demonstrated an increased prevalence during the perimenopausal years, with prevalence rates being lower both before and after the time of the menopause (Figure 4.2a).

Conditions in Sweden are extremely favorable for epidemiological studies, in particular longitudinal studies. The Swedish population register, with its personal number system, provides up-to-date information on the total population and can be used to obtain random and, in some cases, representative subgroups of the total population for the purpose of epidemiological studies. There are several large population-based studies from Sweden describing the prevalence of UI in women. Figure 4.3a illustrates the results from two independent studies of UI in women. In both studies, prevalence was restricted to women who had urinary leakage at least once per week. Although the study performed by Samuelsson and coworkers [25] was undertaken in a rural area and that by Simeonova et al. [26] was carried out in an inner city, there are strong similarities between the results of the two studies, with a linear increase in the prevalence of UI that continues over the perimenopausal years.

In contrast, another Swedish population study [23] (Figure 4.3b) failed to demonstrate any increase in the prevalence of UI between women aged 46 and 56 (prevalence 12% for both cohorts). The majority of 46-year-old women were premenopausal, whereas the majority of 56-year-old women were postmenopausal. There were no differences in prevalence rates between pre- and postmenopausal women within the respective birth cohorts (Figure 4.4a). Thus, there was no evidence to suggest that the prevalence of UI increased at the time of the last menstrual period. The 5th International Consultation on Incontinence after an evaluation of the available literature came to the conclusion that the menopause per se did not influence the prevalence of UI. However, this is not necessarily synonymous with the fact that the reduction in circulating estrogens is not associated with an increase in the prevalence of UI in women after the menopause.

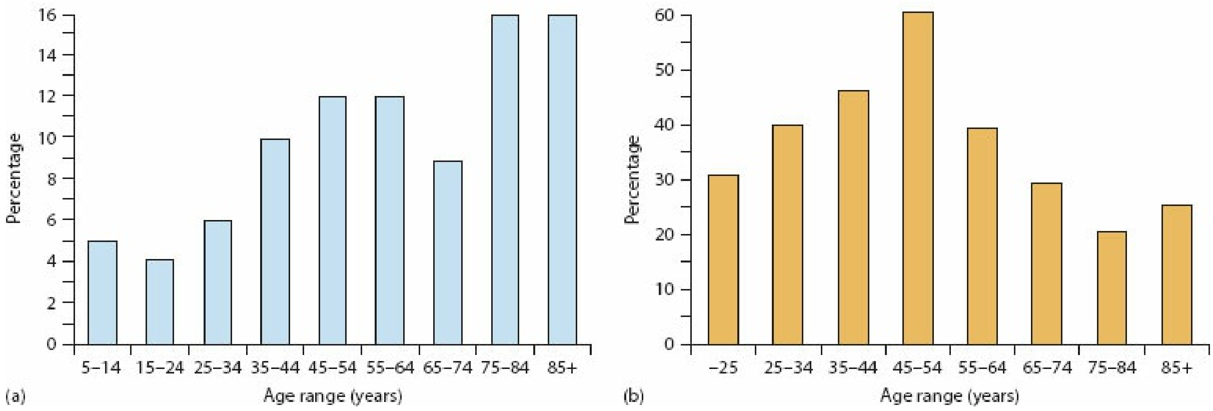

Figure 4.1 Comparison of the prevalence of female urinary incontinence in two British studies. (a) The study by Thomas et al. [6] was performed in 9323 British women, and (b) the study by Jolleys [14] was performed in 833 British women.

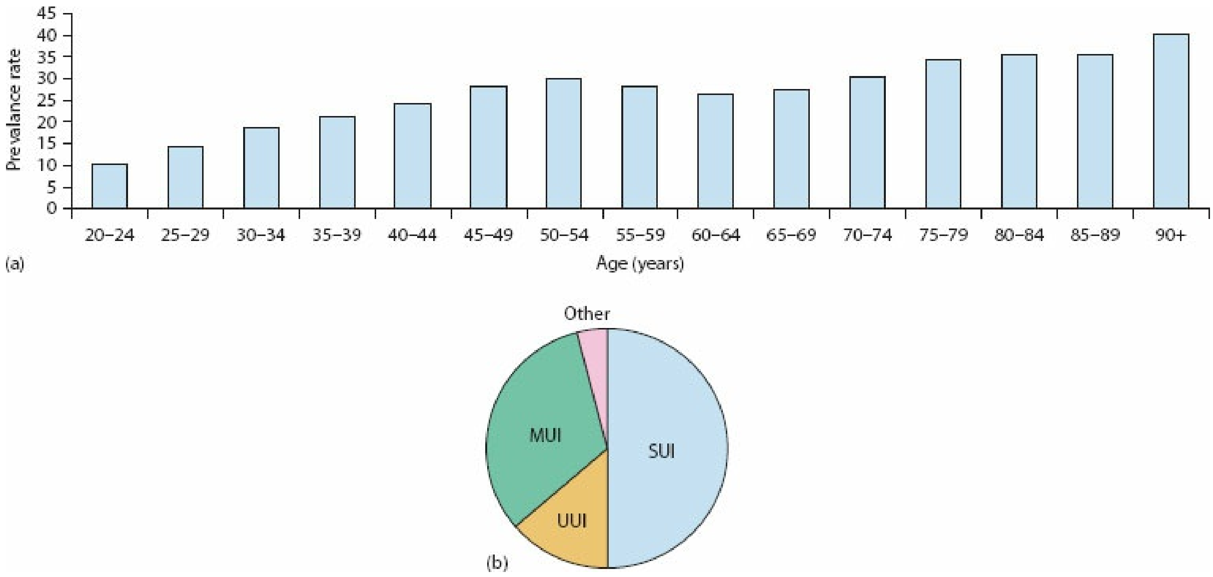

Figure 4.2 Prevalence of urinary incontinence in Norwegian women grouped (a) by age and (b) type of

incontinence. Abbreviations: MUI, mixed urinary incontinence; SUI, stress urinary incontinence; UUI, urge urinary incontinence. (Based on data from Hannestad YS et al., *J Clin Epidemiol*, 53, 1150, 2000.)

The prevalence of UI in women has been compared with the prevalence in men of the same age in two large Swedish studies [23,35]. As can be seen from the results illustrated in Figure 4.3b, there is a higher prevalence of UI in women than in men in all the age groups studied. In general, the prevalence of UI is approximately three times more common in women than in men.

The majority of the population studies referred to in this chapter have been performed by means of postal questionnaires. In several of the studies, attempts have been made to determine the proportion of women suffering from the different types of urinary leakage, i.e., stress urinary leakage (SUI), urge urinary leakage (UUI), and mixed urinary leakage (MUI). The distribution of the various types of incontinence in the large Norwegian study by Hannestad et al. [27] is shown in Figure 4.2b. In the literature, SUI tends to dominate among younger women, while the number of women with urge incontinence and mixed incontinence increases with age.

Further studies [27,30–35] have added important information on the prevalence of incontinence in women younger than 30 and older than 80 years of age, particularly for prevalence of incontinence by type. These studies are consistent with previous studies reporting that older women are more likely to have mixed and urge incontinence, while young and middle-aged women generally report stress incontinence. Overall, approximately half of all incontinent women are classified as stress incontinent. A smaller proportion are classified as mixed incontinent and the smallest fraction as urge incontinent. A recent study that included the entire adult age range by Hannestad et al. [27] demonstrated a fairly regular increase in prevalence of mixed incontinence across the age range and a decrease in prevalence of stress incontinence from the 40–49-year-old age group through the 60–69-year-old age group. There is no hard evidence for different prevalences of UI among Western countries. However, comparing prevalence between countries based on separate studies is difficult due to differences in methods and definitions, as well as language, cultural, and social differences. One of the few studies to estimate the prevalence of UI in more than one country found similar prevalences of any UI (41%–44%) in 3 of the 4 countries examined (France, Germany, and United Kingdom) but a lower prevalence (23%) in the fourth country (Spain) [28]. There was no apparent reason for the lower prevalence in Spain.

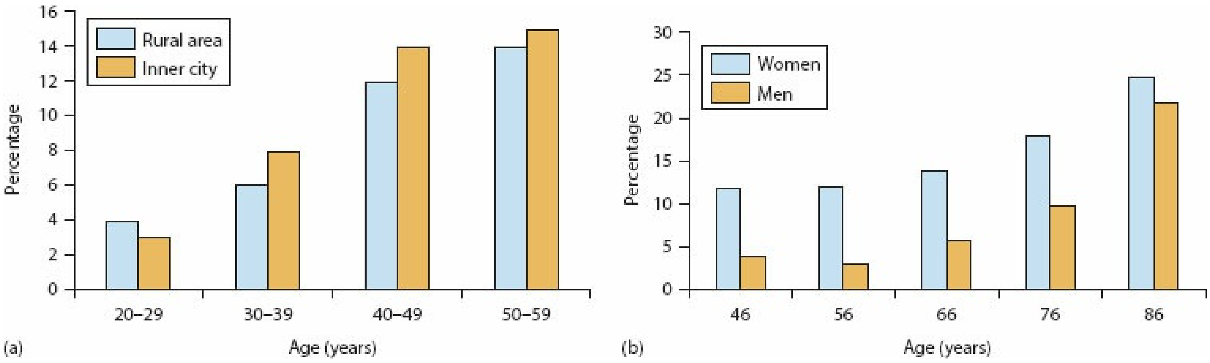

Figure 4.3 Comparison of the prevalence of urinary incontinence: (a) in two population-based studies of Swedish women in a rural area (Samuelsson et al. [25]) and in an inner city (Simeonova et al. [26]) and (b) in two population-based Swedish studies in women (n = 7459) [23] and men (n = 7763) [35] of the same ages.

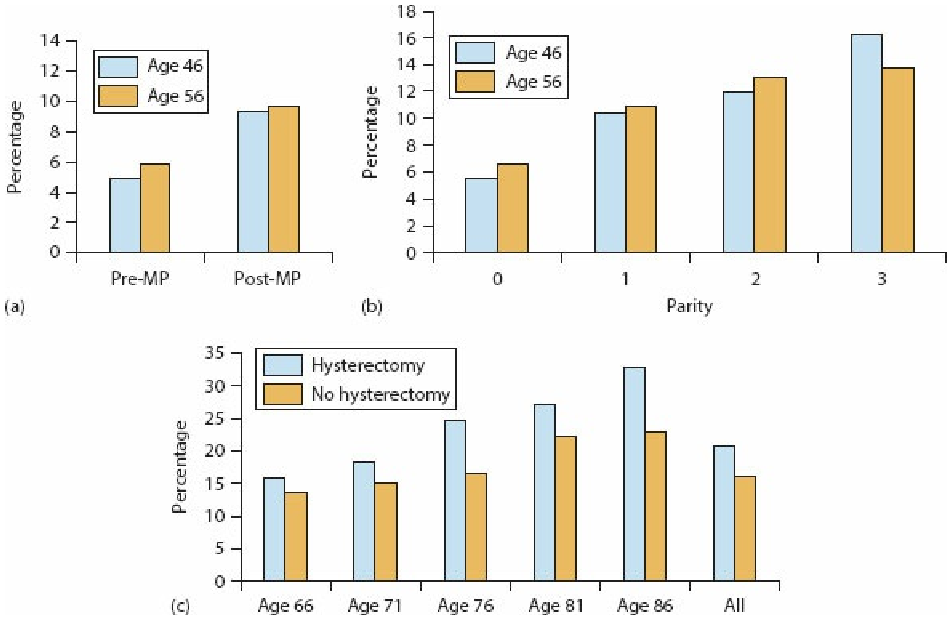

Figure 4.4 Prevalence of urinary incontinence: (a) in a random sample of 46- and 56-year-old women grouped according to menopausal status, (b) in a random sample of 46-year-old (n = 1530) and 56-year-old (n = 1638) women grouped according to parity, (c) in a random sample of 66-, 71-, 76-, 81-, and 86-year-old women grouped according to history of hysterectomy. (Data from Milsom I et al., *J Urol*, 149, 1459, 1993.)

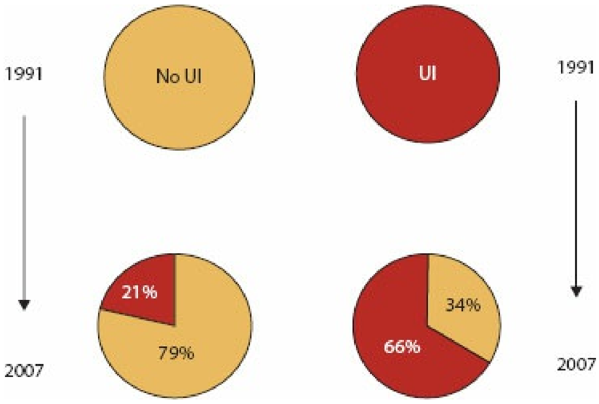

Figure 4.5 The incidence and regression of urinary incontinence in the same women assessed in 1991 and 2007. (From Wennberg A et al., *Eur Urol*, 55, 783, 2009. With permission.)

UI is, however, not static but dynamic and many factors may contribute to incidence, progression, or remission. There are only a few studies describing progression as well as remission, in the short term, of UI in the general population as well as in selected groups of the population. The mean annual incidence of UI seems to range from 1% to 9%, while estimates of remission are more varying, 4%–30% [36–38].

Wennberg et al. [36] studied the prevalence of UI in the same women (aged ≥20 years) over time in order to assess possible progression or regression. A self-administered postal questionnaire with questions regarding UI, OAB, and other LUTS was sent to a random sample of the total population of women in 1991. The same women who responded to the questionnaire in 1991 and who were still alive and available in the population register 16 years later were reassessed using a similar self-administered postal questionnaire. The overall prevalence of UI increased from 15% to 28% ($p < 0.001$) from 1991 to 2007, and the incidence rate of UI was 21%, while the corresponding remission rate was 34% (Figure 4.5).

Thus, in summary, when reviewing the literature, there is considerable evidence to support the theory that the prevalence of UI increases in a linear fashion with age as shown in Figure 4.6, which includes pooled data from 19 epidemiological studies where UI was reported to occur at least once per week.

FACTORS INFLUENCING THE PREVALENCE OF UI

Risk factors described in the literature are shown in Table 4.1 [3,30–32,39–41]. For the majority of these risk factors, there are at present no controlled trials demonstrating that intervention reduces the incidence, prevalence, or degree of severity of UI.

The influence of various factors on the prevalence of UI was evaluated by means of a postal questionnaire in women aged 46–86 years resident in the city of Gothenburg, Sweden [23]. Age, parity, and a history of hysterectomy were all correlated to the prevalence of UI, which increased in a linear fashion from 12.1% in women 46 years of age to 24.6% in women aged 86 years of age. The prevalence of UI was greater in parous women compared to nulliparous women, and prevalence increased with increasing parity (Figure 4.4b). UI was more prevalent in women who had undergone a hysterectomy (Figure 4.4c). The prevalence of UI was unaffected by the duration of previous oral contraceptive usage, and there was no evidence to suggest that the prevalence of UI increased at the time of the last menstrual period (Figure 4.4a).

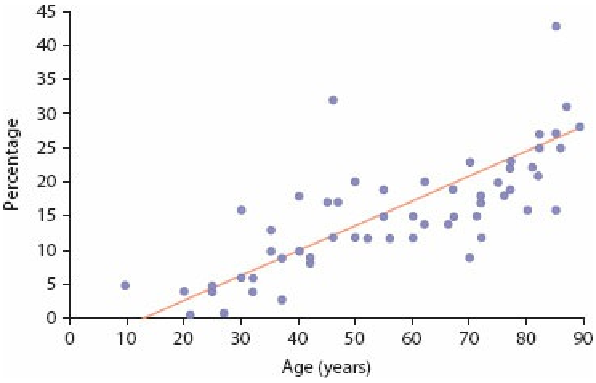

Figure 4.6 Prevalence of female urinary incontinence (≥1/week), which affected the woman's way of life (summary of 19 population studies). (Based on Hellström AL et al., Health economics, in Treatment of urinary incontinence, The Swedish Council on Technology Assessment in Health Report on Urinary Incontinence, SBU, Stockholm, Sweden, 2000.)

Several studies suggest that the risk of UI "runs in the family" [3,29,40–43]. Family history studies have found a twofold to threefold greater prevalence of stress UI among first-degree relatives of women with stress UI compared to first-degree relatives of continent women. In the Norwegian Nord-Trøndelag health survey Epidemiology of incotinence in the country of Nord-Trondelag (EPINCONT), daughters of mothers with UI had an increased risk of stress incontinence, mixed incontinence, and urgency incontinence [29]. In general, the risk was somewhat higher for sisters of a woman with UI than for daughters.

Chronic illness

Studies from the Swedish twin register indicated that heritability contributes to the liability of developing UI. The authors presented evidence that for both disorders genetic and nonshared environmental factors equally contributed 40% of the variation in liability [40,41]. Although study methodology and the magnitude of the risk estimates vary, studies on familial transmission of incontinence are in agreement [29,40,41] in which having a first-degree female family member with stress UI increases the risk for an individual becoming afflicted by the same disorder.

Many studies have assessed the influence of pregnancy and in particular vaginal delivery on the risk of developing UI. The prevalence of UI in nulliparous women of childbearing age has been reported to be 10%–15% [42–44]. UI preceding pregnancy in nulliparous has been shown to be a strong indicator for increased prevalence of UI 4–12 years postpartum [45,46]. Pregnancy in itself, independent of labor and delivery practices, seems to be a risk factor for postpartum UI [47,48] especially if the incontinence started during the first trimester [49]. During pregnancy, the prevalence of UI increases with gestational age [50] so that more than half of all women report UI during the third trimester [51–53]. Stress UI and mixed UI increased the most during pregnancy compared to before pregnancy, whereas urge UI did not change during the same period [54]. During the first 3 months, postpartum UI prevalence was 30% and most women had stress UI [55]. In uncomplicated courses of pregnancy and labor, UI usually declines rapidly during the first 3 months following childbirth, indicating that most symptoms are part of a normal pregnancy and delivery [47]. Several studies have also demonstrated that postpartum UI is a risk factor for UI after longer (7 months to 6 years) terms of follow-up [48,56–58].

The first delivery is considered to increase the prevalence of UI the most, and recent studies have demonstrated a further increase for each delivery [23,59–62]. Many cross-sectional and several longitudinal studies show a protective effect of CS for UI [63–66]. BMI is considered to be an established risk factor for UI [61], whereas the association between UI and age is complicated by confounders [67].

OAB and Other LUTS

In recent years, several epidemiological studies have also been conducted in order to better understand the prevalence and the impact of OAB and other LUTS. OAB is defined as the presence of urgency and frequency (either daytime or nighttime), with or without UI [5]. OAB is often divided into OAB without UI (OAB_{dry}) and those with OAB and UI (OAB_{wet}). The reported prevalence of OAB in females varied between 7.7% and 31.3%, and in general prevalence rates increased with age [68–72]. OAB has been shown to be associated with other chronic debilitating illnesses such as depression, constipation, and diabetes as well as neurological illnesses. OAB is commonly associated with other LUTS, which was well illustrated by the cluster analysis performed by Coyne et al. [73].

The prevalence of OAB symptoms was estimated in a large European study involving more than 16,000 individuals [68]. Data were collected using a population-based survey (conducted by telephone or face-to-face interview) of men and women aged ≥40 years, selected from the general population in France, Germany, Italy, Spain, Sweden, and the United Kingdom using a random, stratified approach. The main outcome measures were prevalence of urinary frequency (>8 micturitions/24 hours), urgency and urge incontinence, proportion of participants who had sought medical advice for OAB symptoms, and current or previous therapy received for these symptoms. The main results of this study are illustrated in Figure 4.7a with the prevalence of OAB symptoms grouped according to age and sex and in Figure 4.7b grouped according to age, sex, and nationality.

The progression or regression of OAB and other LUTS was studied by Wennberg et al. [36] in the same women (aged ≥20 years) followed over a period of 16 years (from 1991 to 2007). The overall prevalence of OAB, nocturia, and daytime micturition frequency of eight or more times per day increased by 9%, 20% ($p < 0.001$), and 3% ($p < 0.05$), respectively from 1991 to 2007. The incidence of OAB was 20% and the corresponding remission rate was 43%. Women with OAB symptoms were classified as OAB dry or wet depending on the presence or absence of concomitant UI. The prevalence of OAB dry did not differ between the two assessment occasions (11% and 10%, respectively), but the prevalence of OAB wet increased from 6% to 16% ($p < 0.001$). Among the women with no OAB in 1991, the prevalence in 2007 were 8% and 12% for OAB dry and wet, respectively. There was a progression from OAB dry to wet in 28%. Remission from OAB dry or wet to no OAB occurred in 50% and 26%, respectively (Figure 4.8).

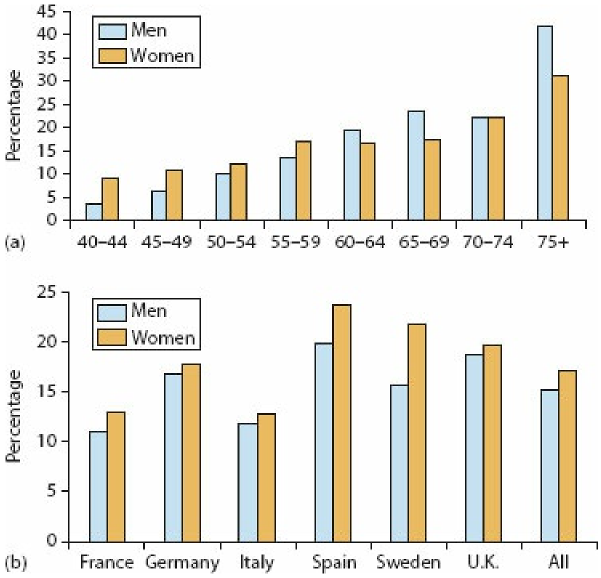

Figure 4.7 Prevalence of overactive bladder symptoms (a) grouped according to age and sex and (b) in a random sample of the total population aged ≥40 years from six European countries. (Adapted from Milsom I et al., *Br J Urol Int*, 87, 760, 2001.)

		2007			
		No OAB	OAB dry	OAB wet	Total (%)
1991	NO OAB	634	64	93	791 (83%)
	OAB dry	52	24	29	105 (11%)
	OAB wet	14	11	28	53 (6%)
	Total (%)	700 (74%)	99 (10%)	150 (16%)	949 (100%)

SOCIOECONOMIC CONSIDERATIONS

The economic consequences of UI and other LUTS have recently been reviewed [4], and there are now numerous reports to support the statement that UI and LUTS have a huge bearing on health-care costs [1,4,74–77]. Prevalence rates vary throughout the world, but a recent review indicated that urge UI rates were particularly high in the Nordic countries [77] and in particular Sweden (Figure 4.9). The economic consequences of UI in Sweden in 1990 were assessed by Ekelund et al. [1]. The estimated annual cost for UI in Sweden at that time was 1.8 billion Swedish crowns. The Swedish health-care budget for 1990 amounted to 93 billion Swedish crowns. Based on the results of this evaluation, the annual costs of UI in Sweden accounted for approximately 2% of the total health-care costs. Ten years later, the annual estimated costs had increased from 1.8 billion Swedish crowns to 2.8–4.4 billion Swedish crowns [78].

Mean life expectancy in the industrialized world is increasing, and in some countries 25% of all persons are at present ≥65 years of age. Thus, the number of women requiring treatment for UI is expected to increase in the future. Another important factor to consider, apart from the numerical increase in the number of elderly women, is the fact that many elderly women of today suffer in silence, accepting these symptoms as a normal part of the aging process. Women who are at present 30 and 40 years of age have other demands on their physical condition and will undoubtedly not accept what their older counterparts accepted later in life.

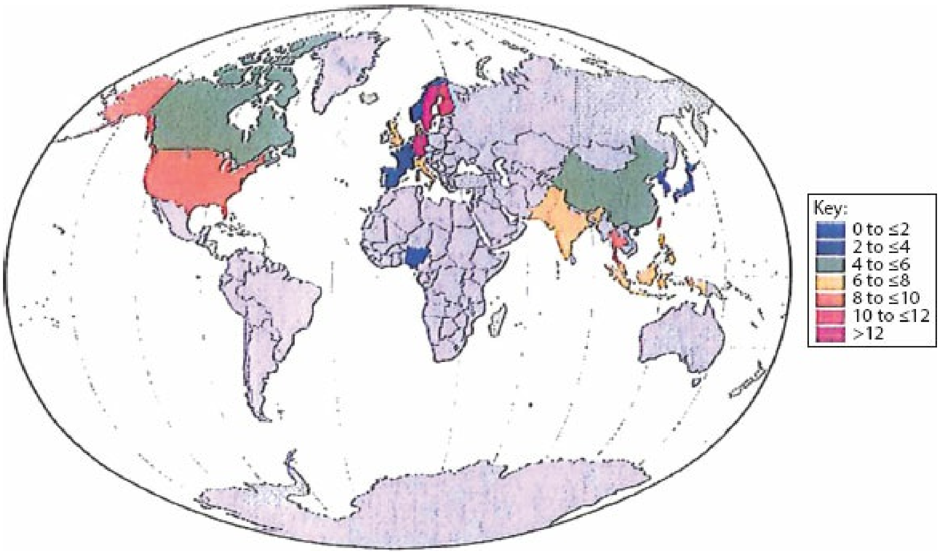

Figure 4.9 World map illustrating urgency urinary incontinence (UUI) prevalence rates for adult women for 2013. Prevalence rates reported in each captured study were adjusted for the current age distribution of the country's population obtained from the International Data Base of the U.S. Census Bureau. Age-adjusted prevalence rates were averaged when more than one study had been performed in a single country. For studies that reported separate rates for UUI, mixed urinary incontinence (MUI), and stress urinary incontinence, the UUI prevalence rate was calculated based on the sum of UUI and MUI rates. (From Milsom I et al., *Eur Urol*, 651, 79, 2014. With permission.)

5 Epidemiology: Australia

Christopher Benness

BACKGROUND

Australia is a developed nation of 24 million people [1] with a small, disadvantaged indigenous population (2.5% of population are Aboriginal). It is a young nation, with its European settlement being less than 250 years ago. Most of the population arrived in various waves of immigration, initially from Europe but more recently from Asia, resulting in a multicultural society. The Australian health system has considerable private sector involvement complementing universal health coverage by the government. Most of the population live in cities on the coastal fringe with good access to healthcare. However, providing high-quality healthcare to the many remote centers in Australia is a challenge.

Australia was one of the first countries to designate urogynecology as a subspecialty area of obstetrics and gynecology. The Royal Australian and New Zealand College of Obstetricians and Gynaecologists has had accredited subspecialists in this area since 1990. Certification in urogynecology requires 3 years training in an accredited unit, following completion of general obstetrics and gynecology training, and passing a written and oral examination [2]. There are currently 35 accredited urogynecologists in Australia and nine training units.

URINARY INCONTINENCE: PREVALENCE

Urinary incontinence is known to be a common condition in women [3], to be multifactorial in pathogenesis [4], and to significantly affect the quality of life of many of its sufferers [5]. It imposes a significant burden on affected individuals, those who care for them, and the health services [6]. The prevalence of a condition is one of the main epidemiological indices and is defined as the proportion of a population having a disease at a point in time. The prevalence of urinary incontinence in Australia has been explored by a variety of authors and studies in the past 30 years, looking at a range of different populations. Chiarelli et al. in 2005 applied the results of a systematic review of the medical literature to the Australian population [7]. They estimated that the prevalence of urinary incontinence in Australian women was 19.3% and that of fecal incontinence in women was 5.3%.

In 1983, Millard conducted a postal survey of 3000 people using a 38-question, self-administered questionnaire [8]. A multistage, cluster-sampling technique was used to select participants. Replies were received from 1256 people (42%) of whom 651 were females. Thirteen percent of the male and 34% of the female respondents had some degree of urine loss. The frequency of urinary loss is shown in Table 5.1. The mean duration of all leakage problems was 8.8 years: 18% reported leakage for less than a year, while 23% had had problems for 15 or more years. The circumstances in which the respondents experienced leakage are shown in Table 5.2 (more than one answer was allowed). The severity of urine loss as quantified by the respondents is shown in Table 5.3. In most cases, the incontinence occurred infrequently and was of minor severity. Nocturnal enuresis was present in 26 women (4%). Thirty-one percent of the women who reported urinary leakage had sought help from a health professional. As other studies have demonstrated [9], parity was a significant factor in the pathogenesis of urinary incontinence, with the prevalence doubling from 20% to 40% with the first child.

In 1999, Chiarelli et al. reported on urinary incontinence prevalence data from the Women's Health Australia project [10]. This longitudinal study involves three cohorts of women: young (age 18–23 years), middle-aged (aged 45–50 years), and older (70–75 years) at the time of the baseline survey. The women were selected randomly from the Australian Medicare database. During 1996, approximately 14,000 women in each of the three groups completed baseline surveys (respectively, 48%, 54%, and 41% of those of each group who were invited to take part). Among other health questions, the participants were asked whether they had leaked urine in the last month "never," "rarely," "sometimes," or "often." The advantages of this study were its large sample size and the representative nature of the sample.

The prevalence of urinary incontinence in young women in this study was 12.8% (95% CI 12.2–13.3); in middle-aged women, it was 36.15% (CI 35.2–37.0), and in older women 35% (CI 34.1–35.9). Parity was significantly associated with the prevalence of incontinence in young women but was less strongly correlated in the other age groups. There was a strong association between any degree of constipation and urinary leakage. In middle-aged women, those with high body mass index (BMI > 25) and constipation were those most likely to experience leakage of urine. Hysterectomy alone had a lower odds ratio for leakage, whereas women who reported a prolapse repair were more likely to leak. Neither current use of hormone replacement therapy nor duration of use was associated with urinary incontinence. At all ages, women who reported leaking urine had scores on the SF36 inventory suggesting a lower quality of life compared with continent women.

A follow-up study related to the Women’s Health Australia project was reported in 2003 [11]. The cohorts had aged by 5 years. The majority of all age groups reported mixed stress and urge leakage with almost 80% of incontinent women over 50 years of age having mixed incontinence. Risk factors for incontinence severity that were identified were raised BMI, high parity, and smoking >20 cigarettes per day.

Table 5.1 Frequency of Incontinence Episodes

	Percentage of respondents		
Frequency	**Male**	**Female**	**Overall**
Often wet	2	4	3
Once a day	2	4	3
Once a week	1	3	2
Once or twice a month	0	4	2
Rarely	8	18	13
Never wet	87	66	76

	Percentage of respondents		
Urinary Loss	**Males (*n* = 79)**	**Females (*n* = 214)**	**Overall**
Always wet	0	2	2
Flooding	0	2	1
Moderate loss	8	5	5
Slight loss	25	41	37
Just a spot	66	49	54

A further longitudinal study based on a cohort of women aged 70–75 years has been reported [12]. These women are part of the Australian Longitudinal Study of Women's Health and a follow-up after 9 years is outlined. Over this time, 14.6% (95% CI 13.9–15.3) of previously continent women became incontinent. Longitudinal models demonstrated an association between incontinence and dementia, falls, BMI, constipation, lower urinary tract infection, and urogenital prolapse. A weaker association was found with stroke and hysterectomy.

The results of a population survey in South Australia were published in 2000 [13]. This was a cross-sectional survey of men and women with 3010 interviews, conducted by trained female interviewers, from 4400 randomly selected households. The prevalence of all types of urinary incontinence in women was 35.3% and in men was 4.4%. Urinary incontinence increased after pregnancy according to parity and age. The highest prevalence (51.9%) was reported in women aged 70–74 years. The prevalence of fecal incontinence in women was 3.5%. Pregnancy (>20 weeks), regardless of mode of delivery, greatly increased the prevalence of major pelvic floor dysfunction, defined as any type of incontinence, symptoms of prolapse, or previous pelvic floor surgery. Multivariate logistic regression showed that, compared with nulliparity, pelvic floor dysfunction was significantly associated with cesarean section (OR 2.5, 95% CI 1.5–4.3), spontaneous vaginal delivery (OR 3.4, 95% CI 2.4–4.9), and at least one instrumental delivery (OR 4.3, 95% CI 2.8–6.6). Other associations with pelvic floor morbidity were age, BMI, coughing, osteoporosis, arthritis, and reduced quality of life scores.

RELATIONSHIP BETWEEN INCONTINENCE AND AGE GROUP

The prevalence of urinary incontinence and its relationship to age group in the Millard study [8] is shown in Figure 5.1 and Table 5.4. There is a rise with increasing age, peaking at 50% in the perimenopausal group (age 45–59 years) with some decline following this. The high prevalence (40%) in those over 70 years is similar to that found in other studies [11]. Urinary stress incontinence was most prevalent in middle-aged women (aged 45–59 years), while urge leakage increased with advancing age and peaked in the over 70s age group. These findings are similar to those of another Australian questionnaire-based study [14] of 542 community-dwelling women aged 24–80 years. The overall prevalence of any urinary incontinence was 41.7% (95% CI 37.2–45.8) with a response rate of 93.4%. Of the 210 women reporting urinary incontinence, 16% reported stress incontinence only, 7.5% reported urge incontinence only, and 18% reported mixed incontinence. Logistic regression revealed a significant association of obesity and parity with stress incontinence. Increasing age, being overweight, and previous hysterectomy were associated with urge incontinence.

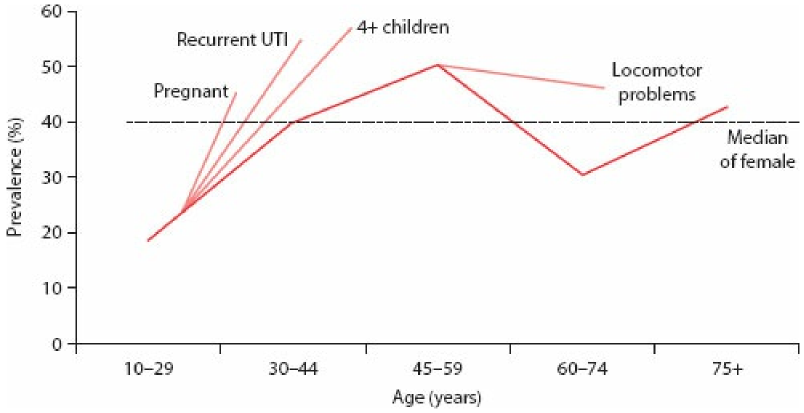

Figure 5.1 Prevalence of incontinence according to age.

Table 5.4 Prevalence of Incontinence and Its Relationship to Age Groups

		Age group (years)				
No. of individuals	October 29	30–44	45–59	60–74	75+	Overall
Sample total	498	354	250	117	37	1256

Wet	25	20	16	11	7	79
	(10)	(13)	(13)	(21)	(44)	(13)

[a] Percentages in parentheses.

Female adolescents with chronic lung disease have been shown by Nixon et al. to have a higher prevalence of urinary incontinence [15]. They assessed 55 adolescents, aged 12–19 years with cystic fibrosis. Forty-seven percent had experienced some urinary incontinence with twenty-two percent experiencing leakage at least twice per month.

INCONTINENCE IN PREGNANCY

An Australian study of the prevalence of urinary incontinence in pregnancy was reported by Chiarelli and Campbell [16]. This was a cross-sectional descriptive study using a structured interview. Women in the postnatal ward of a large teaching hospital were approached (336) and 304 participated (90%). Overall, 64% reported stress urinary incontinence during pregnancy. In the last month of pregnancy, 57% reported stress incontinence while 42% had urge incontinence. Of those experiencing incontinence, 18% reported severe urine loss. The leakage had started during the first trimester in 8%, in the second trimester in 18%, and in the last trimester of the most recent pregnancy in 47%. For 20% of those with leakage, it had begun in a previous pregnancy, and in 6%, it had begun after the birth of a previous child. For 49%, leakage was not at all bothersome, 31% found it a little bothersome, 16% quite bothersome, and 4% extremely bothersome.

Data analysis showed continence status to be significantly associated with delivery mode, parity, and chronic cough. Women who had had previous deliveries were 2.5 times more likely to be incontinent of urine than those who had no previous deliveries or had only cesarean sections. Those who reported previous forceps delivery were 10 times more likely to be incontinent than those with no prior delivery.

CHILDHOOD INCONTINENCE

In the Millard study [8], 21% of respondents recalled bed-wetting as a child and this was equal in males and females. It was more common in higher socioeconomic families. Of these childhood bed-wetters, 11% still wet the bed as adults. They were also at increased risk of developing urge incontinence in adult life.

The prevalence of childhood enuresis in Australia has been studied by Hawkins [17] in 1962 and by Bower et al. [18] in 1996. The former took a sample of 1000 children from one general practice and found a prevalence of nocturnal enuresis (of one or more nights per week at school age) of 18%. The Bower study used a self-administered questionnaire distributed to parents of children 5–12 years of age. Of the 3111 parents approached, 2292 (74%) responded. Nocturnal enuresis occurred in 18.9% of the children and 5.5% had daytime incontinence, while 4.4% had both day and night wetting. Sixty percent of the children with enuresis were male. Only one third of the families with enuretic children had sought professional help. A positive family history was more common in the enuretic children (70%) compared with the dry children (44%).

INCONTINENCE IN INSTITUTIONS

A Sydney study of 1659 residents of nursing homes found that urinary incontinence affected 77%, and that 25% of nursing staff time was spent dealing with urinary leakage [19]. The long-term care of looking after such residents is expensive and is estimated to cost more than Aus$500 million each year.

Also, the importance and association of incontinence and the increasing prevalence of falls in the elderly has been clearly documented [20]. The odds ratio of sustaining a fall is 1.45 (95% CI 1.36–1.54) in the presence of any type of urinary incontinence.

Table 5.5 Prevalence of Urinary Symptoms in Aboriginal Group

Symptom	**Frequency (%)**
Frequency	39
Urgency	40
Stress Incontinence	48
Urge incontinence	30
Stress and Urge Incontinence	23
Recurrent UTIs	5

ABORIGINAL POPULATION

The indigenous Australian population comprise a small part of the population but have a higher prevalence of most medical disorders than other Australians. A prevalence study of lower urinary tract symptoms was undertaken in rural, community-dwelling Aboriginal women [21]. A questionnaire was administered by a female practitioner, in a face-to-face interview, to 151 rural Aboriginal women. The women interviewed were recruited from the community and had not presented for medical attention. The mean age of the group was 39 years (range 16–69). With 35% having had five or more confinements, 87% were parous. Forty percent of the women were peri- or postmenopausal. Fifty-six percent reported symptoms of urinary incontinence. The prevalence of urinary symptoms in this group is shown in Table 5.5. Of the total group, 48% reported stress urinary incontinence, 30% had urge incontinence, and 23% complained of both stress and urge incontinence. Of those with stress incontinence, it occurred frequently in 30%. Urge incontinence occurred frequently in 38% of those with this problem. Among all the women surveyed, 46% were troubled by their urinary symptoms and 89% of them wanted treatment. Thirty-one percent had sought medical advice, but most had not found it helpful.

6 Epidemiology: Asia

S.S Vasan and Reena Mallesh

INTRODUCTION

Urinary incontinence (UI) is a major clinical problem that has a profound effect on the quality of life and activities of daily living [1–3]. Women with UI report fear, shame, and humiliation and worry about the odor of urine from pads and wet underclothing [4]. UI is physically debilitating and socially incapacitating and is associated with loss of self-confidence, feelings of helplessness, depression, and anxiety [3].

Many adults suffer from UI, and the financial, physical, emotional, psychological, and social impacts are demoralizing and distressing [5–7]. UI has become a costly public health problem [6]. In the United States, it is estimated that direct health costs of UI among older people amount to more than $26 billion per year, an average of $3565 for each incontinent older person [8]. No estimate of health care costs of this kind is available in Asia.

UI is a general problem among older people [5]. Postmicturition dribble and continuous leakage are both common forms that arise in later life. Many incontinent older people in Asia and elsewhere do not talk about their UI or report it to physicians. This is partly due to their limited understanding of UI and also because they fear social rejection. Indeed, UI is underreported and underdiagnosed across all age groups [9–13]. Thus, no accurate estimate of UI is available for people across the age spectrum. Almost all studies, however, confirm that prevalence increases with age [5–11,14–16] and that prevalence is higher among women than among men at all ages [5,7,11,17–19]. The prevalence among older people living in institutions also is higher than among their community-dwelling counterparts [5,7,20,21].

The Agency for Health Care Policy and Research in the United States has estimated that 15%–35% of people aged 60 years and above living in the community have experienced some degree of UI [5,22–25]. Burgio and Locher [23] reported that 20%–30% of older people aged above 65 living in the community suffer from UI. It is also estimated that at least 50% of nursing home residents are incontinent [17,20,23,24,26]. Yarnell and St. Leger [27] reported that between 40% and 60% of nursing home residents are incontinent. According to Tobin [28], the higher prevalence of UI among people living in residential care facilities is related to their increased average age and to the increased prevalence of physical and mental morbidity.

Studies of the prevalence of UI suggest that it is widespread among women of all ages [29]. The probability of incontinence increases with age [30–32], and the nature of incontinence changes from stress incontinence to urge incontinence [33] with increasing age. This is due to an increased prevalence of multiple disorders and organ dysfunction in the elderly. This change has significant implications for clinical management [34]. While stress incontinence is typically managed with pelvic floor muscle training, with or without neuromuscular electrostimulation and surgery, management of urge incontinence might also include a bladder training program, transcutaneous electrical stimulation aimed at the spinal micturition reflex center, and drug therapy [35,36].

EPIDEMIOLOGY OF UI

Throughout Asia, UI remains a sensitive and taboo subject, and there is a need for more open discussion. For the sufferer, UI brings stigmatization, social embarrassment, loss of self-esteem, and loss of face, all of which prompt widespread underestimation and underdiagnosis [13]. There have been few systematic studies of the prevalence and impact of UI among older people in Asian countries.

This chapter reviews the prevalence and severity of UI within Asia with a discussion of the epidemiology of UI together with a systematic review of prevalence within the community [37–39]. Some of the factors assessed include

- Age/gender segments within the population

- Risk factors for incontinence
- Analysis of incontinence prevalence estimates
- Recommendations for studies to reliably determine the prevalence of incontinence within the Asian population

In one of the first pioneering studies done in Asia [40], the prevalence and risk factors of UI in a community-residing older population in Japan were assessed by data collected from home visits with a response rate of 95.4%. The prevalence of any degree of UI was 98/1000 in both sexes and 34/1000 of the population was incontinent of urine on a daily basis. Although there was an increasing prevalence with age, there was no greater prevalence in women. Risk factors were age >75 years, poor general health as measured by activities of daily living, stroke, dementia, the absence of participation in social activities, and poor quality of life.

In another multihospital epidemiological study [41] to elucidate the prevalence and characteristics of UI in elderly inpatients throughout Japan, all patients were evaluated by medical doctors for the following parameters: age, sex, duration of hospitalization, activities of daily living, medical diagnosis, the presence or absence of UI, type of UI, and therapy for UI. The prevalence of UI in patients under 70, 70–79, 80–89, and over 90 years old was 59.3%, 67.7%, 79.8%, and 82.2%, respectively. Overall, 1142 patients (72.0%) suffered from UI. Cerebrovascular disease was the major cause of admission to hospital in patients with UI (37.0%). The most frequent type of UI was functional UI, which was seen in patients who were mentally and/or physically unable to go to the bathroom without aid (21.5%). Specifically, 38.1% of patients in geriatric hospitals were diagnosed as having functional UI, in contrast to only 3.9% of patients in nongeriatric units. In patients with dementia, 88.7% were incontinent, whereas in patients without dementia, the prevalence of UI was significantly lower at 51.5% ($p < 0.001$). Another predisposing factor for UI was urinary tract infection (UTI). The prevalence of UI in patients with and without UTI was 87.8% and 59.5%, respectively ($p < 0.001$). Almost all patients with poor activities of daily living (who were bedridden) suffered from UI (98.5%). On the other hand, UI was less frequent in patients who could walk (26.9%). Pad (42.8%) and indwelling bladder catheter (18.3%) were the major means of containment of incontinence, whereas behavioral therapy (4.9%) and surgery (0.5%) were less common.

Yoshida et al. [13] examined the prevalence and risk factors of UI and potential factors hindering individuals from seeking treatment for UI among a community-dwelling population aged over 40 years. Data were collected by mailing a 23-item UI questionnaire to a random sample of community-dwelling individuals aged 40–75 years ($n = 3500$) in seven towns of Shiga Prefecture, Japan. The overall response rate was 52.5%. Prevalence of UI for male and female respondents was 10.5% and 53.7%, respectively. The incidence of urge incontinence increased with age in the male group. In women, stress incontinence was prevalent at all ages and the incidence of urge incontinence increased over 70 years of age. UI was more likely as activities of daily living limitations and cystitis increased. Women with a history of hysterectomy or diabetes mellitus and men who had had a stroke were at increased risk for UI. Of those who reported UI, only 3% had ever consulted doctors or other health-care professionals concerning it, 25% recognized their condition as a disease, and 38% considered it curable by appropriate treatments. In addition, 63% regarded UI as an unavoidable consequence of aging, 63% considered their condition was embarrassing, and 54% were reluctant to seek treatment from a health professional.

Lee [42] assessed the impact of UI in older Chinese care home residents in Hong Kong by a cross-sectional study using face-to-face interviews with a questionnaire mainly composed of closed-ended questions. The study was conducted at two selected elderly homes and one elderly center. The sample was composed of 92 elderly home residents and 122 elderly center users. Fultz and Herzog's [18] modified operational definition of the severity of UI was used to measure respondents' levels of UI. Specht and Maas's [21] concept of social impact was used to assess respondents' social-life suffering. It was reported that prevalence of UI increased with adult age and that incontinence affected women more than men. About 86.1% of the incontinent respondents experienced negative social impact. There were no statistically significant differences between levels of incontinence and social impact on older respondents' employment, social, family, financial, and physical conditions. Also, there were no significant differences between levels of UI and the reported levels of social impact.

OPERATIONAL DEFINITION OF IMPACT OF UI ON SOCIAL LIFE

Specht and Maas's [21] concept of social impact was adopted with modifications. To measure the adverse impact on sufferers with UI, nine complaints were developed and grouped into the following five subscales: employment, social, family, economic, and physical well-being. To measure the level of suffering (a functional issue), an operational definition of social impact was developed using the following dichotomous (yes/no) criteria:

1. Limitation of job opportunities (employment)
    a. Reductions in employment opportunities
2. Negative impact on social life (social)
    a. Restrictions on opportunities for participation in social activities
    b. Restrictions on participation in outings
    c. Need for cumbersome precautions while going out
3. Negative impact on family life (family)
    a. Need for family help
4. Negative impact on finances (economic)
    a. Increase in daily expenditure
5. Negative impact on physical condition (physical well-being)
    a. Fear of odor
    b. Fear of leakage
    c. Affect on personal appearance

It is generally assumed that moderately to severely incontinent older people experience more impact on their social lives than mildly incontinent people. Contrary to these assumptions, this study found no statistically significant differences in social impact at different levels of UI. Also, there is no significant difference in terms of the impact of moderate to severe incontinence relative to mild incontinence in older sufferers. This is noteworthy as it appears that the level of UI is not a crucial factor in determining impact on older peoples' social lives. The implication is significant; negative impact on incontinent respondents' social lives is basically unique, universal, undeniable, and unavoidable. The social impact on the entirety is the same and should be treated as "actual and real."

Theoretically, the result has four possible explanations: adjustment, habituation, social comparisons, and impression management. Moderately to severely incontinent older people may adjust to the adverse impacts of UI as time goes by or through whatever means available to handle the symptoms. The practice of adjustment and the feeling of habituation will actually reduce the significance of social impact. Additionally, moderately to severely incontinent older people frequently rely on social comparisons in making their social-impact appraisals. They assume that the social impact will become increasingly serious for their peers, while theirs will remain stable. The function of adjustment, habituation, and social comparisons is to uphold the self-esteem and self-worth of those with UI. This behavior helps them build up a better self-image and a positive impression among peers.

People with moderate to severe incontinence suffer from adjustment, habituation, and social comparisons, and impression management may effectively reduce the social impact. Methodologically, measurement and sample problems are two possible reasons for the statistically insignificant differences between the levels of incontinence. First, the measures may not be sensitive enough to detect the difference. Second, the sample is too small to allow for significant and powerful testing of the impact of incontinence. More studies are needed to further explore the social impact between levels of UI.

In a Korean telephone survey of the community by Won-Hee Park and colleagues [43] to estimate the prevalence of UI in females between 30 and 75 years, 1300 were interviewed (86.9% response rate). Overall, UI was reported by 40.8%, and 22.9%, 3.1%, and 14.9% reported pure stress, urge, and mixed UI, respectively. The prevalence of stress, urge, and mixed UI generally did not increase with age. Urge and mixed UI had a greater impact than stress UI on daily tasks ($p < 0.001$), social life ($p < 0.001$), depression or anxiety due to UI ($p < 0.001$), worry about UI ($p < 0.001$), sex life ($p < 0.001$), wearing of protection due to UI ($p = 0.011$), and quality of life ($p < 0.001$). In subjects with pure stress UI, 28.3% reported impaired quality of life compared with 43.9% and 43.8% of subjects with urge and mixed UI. Among these, willingness to seek medical consultation for their problem was seen in 19.1% (stress), 20.0% (urge), and 25.8% (mixed) of urinary incontinent individuals (Tables 6.1 and 6.2). A study has also been performed to estimate the prevalence rate of UI in a representative sample of women aged 50–65 years, using multistage sampling in South Jordan (Karak, Taffileh, Aqaba) in the Middle East [44]. The study was to assess the relationship between UI (stress and urge) and the following variables: age and parity, diabetes mellitus, UTI, body mass index (BMI), medications (diuretics), menopause, history of hysterectomy, and poor mobility. A questionnaire, which was preliminarily tested in a pilot study, and face-to-face interviews were used as the instrument for data collection. Approximately one-third of respondents had UI; 23.1% had stress UI, 26.4% had urge UI, and 18.1% had the mixed type. Prevalence rate of UI was 56.3% for women suffering from UTI and 50% for those who use diuretics. Approximately 54% of women who needed help to move around inside their house complained of UI. High prevalence rates were also observed with parity of five to six (43.5%), menopause (39.7%), and obesity (39.3%) and in diabetic women (35%). High prevalence rates of stress incontinence were found in women suffering from UTI (37.5%); in women using diuretics (39.5%), if parity was 5–6 (34.8%); and in women with a past history of hysterectomy (28.6%). Stress UI was found to increase with an increase in the BMI. The associations between urge incontinence, BMI, UTI, use of diuretics, and ability to go around inside the house were all statistically significant.

A survey of 11 cities in 11 different countries by the Asia-Pacific Continence Advisory Board (APCAB) established an overall prevalence of 12.2% (range 4.6%–23.1%) among both sexes and all age groups in these communities [45]. A Singaporean physician reported prevalence rates of 5%–15% for UI among older people living in his community [10]. In addition, more than one in five older hospital patients suffered from UI, with prevalence among nursing home residents of about 50% [10]. The APCAB study was conducted in the Philippines, Singapore, Malaysia, Thailand, and Indonesia, which was later expanded to 11 countries to determine the magnitude of UI in the region. In Thailand, the prevalence was 17%; in Taiwan, 12%; and in the Philippines, 13%. China and Singapore were reported to have the lowest prevalence rate of only 4%.

The study aimed to establish the prevalence of UI, identify the demographic factors related to its occurrence, and ascertain the determinants for seeking help for this condition among the female population of Southeast Asia.

A 34-item multiple-choice-type questionnaire–based assessment was designed to determine the presence of UI, defined by the inappropriate leakage of urine, its associated symptoms and the resulting degree of bother, and the action taken to address the condition. This questionnaire was translated into the local dialects, was validated in each country, and was administered by medically trained personnel to randomly selected women consulting at outpatient clinics for nonurologic or nongynecologic problems. The survey was conducted in a total of 10 centers: two in the Philippines, one in Singapore, two in Malaysia, one in Indonesia, and four in Thailand.

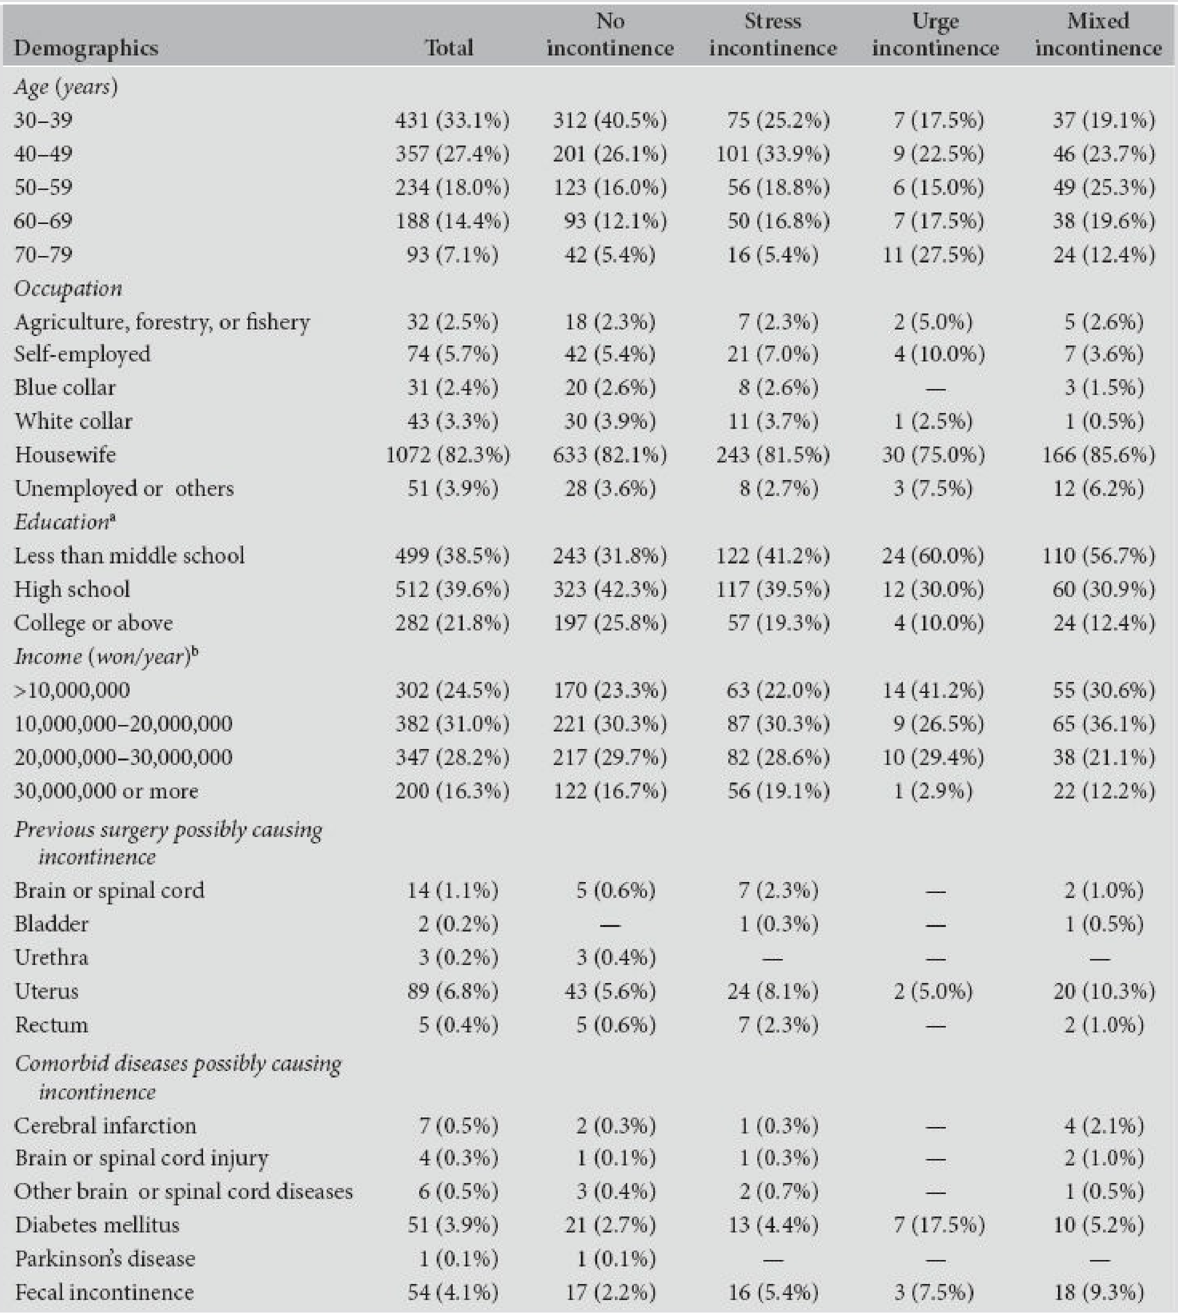
The first part of the questionnaire included questions on population demographics such as age, civil status, parity, educational attainment, occupation, monthly family income, and place of residence. The general voiding pattern was established by noting the normal daytime and nocturnal voiding frequencies. The main body of the questionnaire focused on establishing the presence of voiding dysfunction, particularly UI and overactive bladder through extensive inquiry on the different symptoms associated with these conditions.

Incontinence as a problem was assessed according to the degree of bother it caused the subject using a scoring system of 0–5 (0 as none, 5 as severe), as well as the need for leakage protection and whether the subject sought help for her condition. The relationship among the occurrence of UI and age, parity, number of vaginal deliveries, occupation, family income, type of toilet used, family history, and place of residence was also analyzed.

Study Population Demographics

Table 6.3 shows the distribution of the study population per country (total respondents 2422). While each age group was well represented (Table 6.4), the population studied was relatively young, with the majority aged below 60 years old and more than 50% younger than 40 years. Study population had 44% who were nulliparous. Among the parous respondents, the majority had had at least two deliveries (Table 6.5). Most of the women were doing office work (Table 6.6). There was a high literacy rate, with more than 85% of the population having had at least a secondary level of education (Table 6.7). The study population was evenly distributed among the income groups (Table 6.8), and at least 60% resided in the urban area (Table 6.9).

Table 6.1 Subject Demographics



Demographics	Total	No incontinence	Stress incontinence	Urge incontinence	Mixed incontinence
Age (years)					
30–39	431 (33.1%)	312 (40.5%)	75 (25.2%)	7 (17.5%)	37 (19.1%)

[b] Missing case, 72.

General Voiding Pattern

The voiding pattern of the study population was analyzed according to the frequency of urination (Table 6.10). The majority voided fewer than eight times during the day, with half of this population voiding between four and eight times. Almost all voided fewer than three times during the night, with nearly one-third not voiding at all at nighttime. Around 72% of the study population voided fewer than eight times per 24 hours.

Prevalence of UI

The prevalence of UI in the study population was 14.8% (359/2422). Nearly half of the incontinent individuals (47.9%) are presented with the mixed type. While less than 10% were presented with urge incontinence, 81 women (22.6%) had stress incontinence (Table 6.11).

Table 6.2 Prevalence and Frequency of Urinary Incontinence

	Stress incontinence	Urge incontinence	Mixed incontinence
Prevalence according to age cohort (years)			
30–39 (n = 431)	75 (25.2%)	7 (17.5%)	37 (19.1%)
40–49 (n = 357)	101 (33.9%)	9 (22.5%)	46 (23.7%)
50–59 (n = 234)	56 (18.8%)	6 (15.0%)	49 (25.3%)
60–69 (n = 188)	50 (16.8%)	7 (17.5%)	38 (19.6%)
70–79 (n = 93)	16 (5.4%)	11 (27.5%)	38 (19.6%)
Total (n = 1303)	298 (100.0%)	40 (100.0%)	194 (100.0%)
Frequency			
Many times a day	6 (2.0%)	2 (5.0%)	9 (4.6%)[a]/8 (4.1%)[b]
A few times a day	1 (0.3%)	2 (5.0%)	17 (8.8%)[a]/13 (6.7%)[b]
About once a day	8 (2.7%)	2 (5.0%)	11 (5.7%)[a]/16 (8.2%)[b]
2–3 times in a week	13 (4.4%)	4 (10.0%)	24 (12.4%)[a]/22 (11.3%)[b]
>1 in a week	270 (90.6%)	30 (75.0%)	133 (68.6%)[a]/135 (69.6%)[b]

Liu et al. [46] assessed the prevalence of UI among Chinese women and its associated risk factors. Using standardized questionnaire, 5467 women with a median age of 46.8 years were randomly sampled from four communities in Shanghai. The study showed a prevalence rate of 23.3% with stress UI at 14.0%, urge UI at 3.0%, and mixed UI at 6.3% all increased with age.

UI risk factors were aging, lack of education, poor rural living environment, intense manual labor, the absence of physical exercise, hyperlipemia, diabetes, nocturia, consumption of greasy food, divorce, chronic pelvic pain, pelvic organ prolapse, frequent UTI, and vaginal delivery without episiotomy.

Lee et al. [47] interviewed 18.4 million Korean adult women in a national survey and showed significant UI in 4.2 million, an overall incidence was 22.8%. The prevalence was slightly lower than other Asian studies.

The survey demonstrated an increasing prevalence from 19 years (2.55%) to a peak prevalence of 37%–42% at ages 55–75 years. UI was 10 times more common in married women than unmarried women.

Stress UI was the most common type of involuntary urine loss experienced by Korean women. Of the incontinent women, 48.8% reported stress UI symptoms only; 7.7%, urge UI symptoms only; 41.6%, mixed UI symptoms; and 1.9%, other UI symptoms.

Lee et al. [48], in a Korean EPIC study, adapted on the basis of the European EPIC study, a unique and first population-based prevalence study of lower urinary tract symptom (LUTS), overactive bladder (OAB), and UI.

LUTS was seen overall in 61.4% of respondents (53.7% of men and 68.9% of women). Storage LUTS was more common in women (44.6% of men and 64.4% of women); however, men showed more incidence of voiding LUTS (28.5% of men and 25.9% of women) and postmicturition LUTS (15.9% of men and 13.9% of women).

Table 6.11 Frequency Distribution of Incontinent Population according to Type of Incontinence

Type	n	%
Stress	81	22.6
Urge	31	8.6
Mixed	172	47.9
Undetermined	75	20.9
Total	359	100.0

Incidence of OAB was similar in men and women at 12.2% (men 10.0% and women 14.3%), with a marginal increase over the age of 40 years.

UI was predominantly seen in 28.4% of women and 2.9% of men, with urge incontinence being the most prevalent in men and stress incontinence in women.

Bodhare et al. [49] conducted a cross-sectional study above the age of 35 years in two villages in rural Andhra Pradesh state in India showed a UI prevalence of 10%. The most prevalent type of incontinence was stress incontinence (57%) followed by urge (23%) and mixed incontinence (20%). Obstetrical factors, parity, age at first delivery, history of forceps delivery, and prolonged labor were factors affecting outcome of UI.

Singh et al. [50], in their single-center obstetrics and gynecology department cross-sectional study attending outpatient department, screened women for UI. The overall UI incidence was 21.87%, of which stress incontinence contributed 73.8%, followed by mixed 16.8% and urge incontinence 9.5%. The prevalence was low in women up to 30 years of age (7.5% in women less than 20 years and 11.6% in women between 21 and 30 years of age). In women above 30 years of age, the prevalence ranged from 27.8% to 42.8% with maximum prevalence in the age group of 61–70 years of age.

Prevalence of UI was higher in the vaginal delivery group (26.84%) compared to the nulliparous women (9.42%) and those with cesarean deliveries (8.59%). Postmenopausal women and women who have had hysterectomy showed higher incidence.

INCONTINENCE AS A PROBLEM

The majority of the population who experienced incontinence in this survey was not bothered or, if so, was only mildly bothered by their condition (Table 6.12). However, a major portion (157/359 or 43.7%) felt that protection from leakage was necessary. Of the 359 affected individuals, 150 (41.8%) sought help for their condition.

Factors Related to the Occurrence of UI

Age, parity, mode of delivery of childbirth, number of vaginal deliveries, occupation, family history, and family income were found to be significantly related to the occurrence of UI. The type of toilet used and the place of residence were not found to be related to the occurrence of the condition (Table 6.13).

Age

Increasing age was found to be significantly related to the occurrence of incontinence. By the age of 40 years, the risk for incontinence was found to be increased by 2.5 times (95% CI: 2.0–3.1). The odds progressively increased to 2.8 times and 3.4 times at ages 50 and 60 years, respectively.

Parity

The majority of the incontinent population was parous. There was a significant correlation between the increasing prevalence of incontinence and higher parity. A woman who had delivered at least once was found to be 2.1 times (95% CI: 1.6–2.7) at risk for incontinence compared to a nulliparous woman. With a parity of more than four, the odds increased to 2.5 times.

*Abbreviation:*NI, not indicated.

Mode of Delivery

There was a higher prevalence of incontinence among those who delivered vaginally, by forceps, or a combination of both; a woman who has given birth vaginally has twice the risk of UI than one who has delivered abdominally.

Number of Vaginal Deliveries

Taking into account vaginal deliveries (including forceps delivery), there was a significant relationship of increasing prevalence of incontinence with a higher number of deliveries. More than one vaginal delivery increased a woman's risk for incontinence to 2.0 times (95% CI: 1.6–2.6). The odds increased to 2.6 times when the number of deliveries reached five.

Occupation

The prevalence of incontinence was highest among those doing manual labor (see Table 6.6). This was found to be statistically significant, with a woman who has done manual labor at 1.6 times (95% CI: 1.3–2.1) the risk of having incontinence.

Family History

The family history of incontinence was significantly related to the occurrence of the condition. A woman with a positive family history was 2.4 times (95% CI: 1.9–3.0) at risk of having the condition as compared to one without.

Family Income

A higher prevalence of incontinence was found among those from the lower-income group, which was found to be statistically significant. A woman earning less than "E" had 1.7 times risk (95% CI: 1.3–2.2) of having incontinence.

Factors Associated with Seeking Help for UI

Of the incontinent population, 42% sought help for their condition, consulting either a specialist or a general practitioner (Table 6.14). Among the factors studied in relation to the likelihood of seeking help for UI, only age and degree of bother were noted to be significant (Table 6.15). Increasing age positively influenced the likelihood of seeking a consultation. A woman of at least 50 years of age is 2.4 times more likely to seek help for her condition compared to a younger woman. This likelihood increases to 2.5 times by age 60 years.

The incontinent female who is moderately bothered (score of at least 3) is 3.7 times (95% CI: 2.0–6.9) more likely to seek consultation for her condition compared to one who is less affected. A severe condition increases this likelihood to 5.1 times (95% CI: 2.5–10.4).

Discussion

Prevalence: Comparison with World Figures

The prevalence of UI in this Asian survey is comparable to the Western figures [51–54] and demonstrates the fact that while the condition may not present as a significant problem, UI is prevalent in the Southeast Asian population. Additionally, this puts into question the presumed fact that UI is more common in those with European ancestry than in those with Pacific ancestry. Thus, it is worthwhile investing time and effort to study the problem, its causes, and its management (Figures 6.1 and 6.2).

Types of Incontinence: Comparison with World Figures

The proportion of females with stress incontinence in relation to the other types appears to be relatively low compared to previous studies citing numbers as high as 50%. This may be due to the fact that the population surveyed is relatively young while stress incontinence is more associated with advancing age. Thus, closer attention to the problem of mixed incontinence may be necessary, being the more prevalent type among Asian females [55–57].

It must be recognized, however, that the classification of incontinence used in many of these surveys is based mainly on symptoms alone and not on any objective parameter. This is a limitation inherent in the study design, as previous studies have noted that symptoms alone do not accurately classify incontinence. Therefore, further studies must be done to verify the discrepancy in the distribution of the different types of incontinence among Asian females compared to their Western counterparts.

The factors found to be related to the occurrence of incontinence were not unexpected. Older age, higher parity, higher number of vaginal deliveries, the increased physical strain associated with manual labor, and the use of a sitting toilet have all been cited and accepted as contributing to the weakness of the pelvic floor leading to incontinence [58]. Aging has been associated with the loss of striated muscle in the area of the urethra leading to impaired continence. The change in the hormonal milieu brought about by aging also affects the ability of the urethral submucosal layer to provide the watertight closure of the female urethra. Childbearing, childbirth [59], and physical straining have been found to cause hypermobility, innervation injuries [60], and connective tissue changes [61] to the pelvic floor leading to loss of support.

Family History, Family Income, and the Occurrence of Incontinence

The significant relation between a positive family history of UI and its occurrence may be indicative of a possible hereditary component to the disease. A congenital predisposition to UI has been proposed, citing a common collagen makeup of the pelvic floor found among the affected group. However, a more likely explanation is the tendency of the members of one family to be exposed to the same type of work and physical stresses that predispose an individual to UI.

It is difficult to explain the reason behind the relationship between family income and the occurrence of incontinence. This factor may be related to parity, with those belonging in the lower-income bracket having a higher parity. In addition, the lower-income group tends to do more manual labor. Thus, it may be necessary to test the interdependence of these factors to see the true relationship between income and UI.

Factors Related to Seeking Help: Possible Explanations

The proportion of the incontinent population seeking help in the APCAB study is higher than most study investigators expected since this condition has been regarded as a rare clinical entity among Asians, though the same is not true for studies in other countries [62]. While this observation is an interesting finding, this high figure may be due to the fact that this survey is institution-based and the population surveyed may be those who are motivated to seek a medical consultation for any disease condition. Therefore, a community-based survey must be undertaken in order to verify this finding.

It is interesting to note that almost one-fifth of those seeking help do so by seeing a traditional medical practitioner. This underscores with high regard that the Asian patient still gives to traditional medical science despite decades of Western medicine with its advances. Further studies must be conducted to determine why this is so. This is important in the creation of efficient and effective programs that aim to encourage the affected population to find the solution to their problem.

It is apparent that demographic data are inadequate to fully explain the occurrence of UI and why an affected individual seeks help for the condition. A more objective assessment and a clinical study of the disease must be undertaken to completely understand its pathophysiology. In addition, a deeper and more exhaustive analysis of the attitude of the population toward the disease and the reasons for seeking consult is warranted. Knowledge gained from this will be valuable in future programs and campaigns to increase awareness of UI and to encourage the affected population and the caregivers to address the problem and pursue its solution.

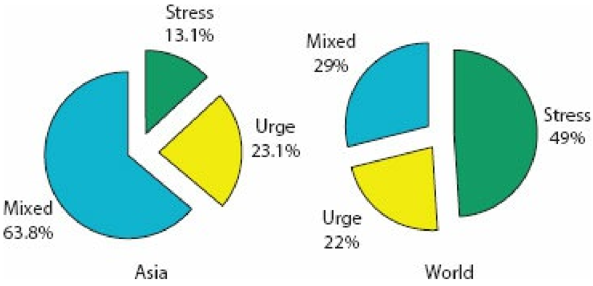

Figure 6.1 Types of urinary incontinence in the world and in Asia. (From Choo MS et al., *Int Urogynecol J Pelvic Floor Dysfunct*, 18, 1309, 2007.)

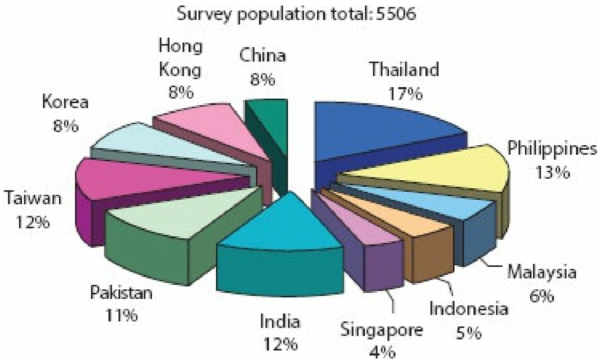

Figure 6.2 Prevalence of urinary incontinence in Asia.

The prevalence of UI among Southeast Asian females appears comparable to worldwide figures. As such, it is a significant and common problem requiring attention. The incontinent female in Southeast Asia is most likely to be older, be of higher parity, and have delivered vaginally, does manual labor, earns less, has a positive family history for the disorder, uses a squatting toilet, and resides in a rural area. A significant portion of the incontinent population has been noted to seek help. This is most likely composed of the older age group and those who suffer from the condition to a greater degree.

CONCLUSION

The occurrence of UI can be described in terms of prevalence (the number of individuals who have incontinence at a point in time), incidence (the number of individuals who newly develop incontinence in a period of time), and the natural history (whether incontinence improves, stays the same, or worsens over time) [63]. Each of these measures varies with factors such as whether the individual is living in the community or in a nursing home and the individual’s sex, age, and racial or ethnic group. Severity of incontinence also varies in its frequency and amount. In addition, incontinence has many different causes.

Prevalence of UI in women living in the community increases with age, from 19% at an age younger than 45 years to 29% in age 80 years and older; the rate levels off from age 50 to age 70 years, after which prevalence again increases.

Information comparing prevalence in racial or ethnic groups suggests that UI is prevalent in all ethnic groups, with some suggestion of higher rates among white women.

With the exception of prevalence of UI, most estimates of the incidence and prevalence of incontinence in adults are based on relatively small numbers of studies. Because these studies used varying definitions of incontinence and different methods of population sampling, the preceding statistics should be considered to be fairly crude estimates.

Although it is impossible to compare surveys between different time periods, countries, or even authors from the same continent or country, the numbers reported seem higher than actually seen in clinical practice, which could be due to many different factors that cause differences in various prevalence rates, which may be due to technical or cultural differences or due to management strategies offered. Hampel [64], in a meta-analysis, reviewed a series of publications for prevalence rates of incontinence throughout the world, which reported stress incontinence as the most prevalent type of all incontinence.

We must have a uniform standardized survey questionnaire [65] that is as applicable in all over the world in developed and developing countries. Without standardizing the questionnaires, we will continue to have reports that may not be meaningful for all interested parties, and it will be impossible to compare the outcomes of different studies. In determining the severity of incontinence, the frequency of UI is important, but equally important is the volume loss. A vast majority of women suffering from stress incontinence with small volume loss will usually cope with their problem and not necessarily seek medical care, whereas an individual who experiences an episode of one big volume loss will be urgently seeking help (Tables 6.14 and 6.15). It is therefore imperative that when obtaining history and performing a survey, volume loss in addition to frequency would be part of the information. Recording this information would make it possible to measure the severity on the basis of a combination of these parameters.

The type of urine loss is also of utmost importance [66]. We all know that there are different types and that each has its own unique signs and symptoms and unique methods of management. Urge type and mixed stress and urge type of incontinence appear to be the most common forms of UI in elderly men and women. If we are to understand UI better, we have to know which type we are dealing with. The correlates of UI are well known.

Finally, conventional epidemiologic [67] studies must incorporate issues relevant to all individuals suffering from incontinence, including quality of life (social and emotional well-being), financial burden, and effects on work and home.

Although UI is common among community-dwelling individuals over 40 years of age, the majority of affected individuals remained untreated due to the lack of knowledge and/or a negative perception of UI [68]. Thus, community education on UI may be needed to increase the number of UI patients who receive treatment.

ACKNOWLEDGMENTS

"A certain amount of the material in this chapter has been taken from work mentioned in the First Edition by Prof. Peter H.C. Lim and Associate Prof. Mela C. Lapitan in their chapter on the subject and updated accordingly by this author," and we also acknowledge the assistance of Mr. Won-Hee Park in updating this chapter.

7 Epidemiology of Female Pelvic Floor Dysfunction in Africa

Stephen Jeffery and Peter de Jong

INTRODUCTION

The impact of pelvic floor dysfunction and urinary incontinence in particular, on the lives of African women, is very different from the experience on any other continent. Stress and urgency urinary incontinence, pelvic organ, and fecal incontinence no doubt affect the quality of life of African women, but by far the heaviest burden Africa carries is the prevailing problem of obstetric vesicovaginal fistulas, and the profound suffering this causes.

Africa has unique problems and challenges. Life expectancy is below 60 years in a large proportion of countries on the continent compared to the world median of 74 years [1]. The total population of Africa is estimated at 1.1 billion [2]. Despite being rich in natural resources, Africa remains the world's poorest continent due to a combination of corrupt governments, human rights violations, high levels of illiteracy, and frequent military conflicts. This clearly impacts on the quality and availability of medical services on the continent.

Obstetric fistulas overshadow all other issues related to pelvic floor dysfunction and are responsible for a huge burden of disease. A major factor affecting the treatment of women with incontinence in Africa is the poor quality of health care. Many women do not have access to even the most basic medical services, not to mention expensive anticholinergic drugs, incontinence pads, and mid-urethral tapes. Access to specialist services is even more confined and usually limited to the large cities. This translates to reduced access to the necessary skills and resources to investigate and treat women with pelvic floor dysfunction.

There are limited data on the epidemiology of pelvic floor dysfunction on the continent. In a literature review on urogynecology research in Africa, Maki et al. [3] looked at the extent and origin of published papers on this subject. The top four countries publishing papers were Nigeria (87 papers), Egypt (71 papers), South Africa (54 papers), and Ethiopia (42 papers). These countries accounted for more than two-thirds of the total number of publications in the 54 African countries. Overall, the number of papers on anal incontinence, prolapse, and sexual function was low. Fistula is appropriately a major focus of incontinence research in Africa. Maki et al. [3] found 200 papers on this subject, but more than half of these originated in Nigeria and Ethiopia. Maki et al. also report that of published papers on nonfistula urinary incontinence, more than a third originated in Guinea. The Central African Republic produced the only paper on patients' perceptions of prolapse, while South Africa produced the only paper in Africa on complications of vaginal mesh. The majority of the published research on sexual dysfunction was on postmenopausal women or in women following genital cutting. Maki's paper highlights the fact that very little is known regarding pelvic floor dysfunction for large areas of the continent.

It is important to appreciate that there are significant hurdles associated with obtaining useful epidemiological data in Africa. One of the problems is the broad range of languages spoken on the continent. UNESCO [4] estimates that close to 2000 languages are spoken, making the collection of robust data difficult. This is compounded by the unavailability of suitable questionnaires. Another issue is a lack of appropriate funding to perform good, representative epidemiological studies. The field of urogynecology and pelvic floor dysfunction is in its infancy on the continent, and until the region develops a sizeable cohort of clinicians with an interest in this specialty, good epidemiological data will not be available.

The available published prevalence data vary extensively between studies. For example, Ojengbede et al. [5] reported a prevalence of incontinence of only 2.8% in a cohort of 5000 women compared to a figure of 70.8% reported by Walker and Gunasekera [6]. Similarly, the extent of bothersome pelvic organ prolapse in Africa remains unknown. Of the few studies, the range is between 3.4% and 56.4% [6–8].

Most doctors underestimate the impact of pelvic organ prolapse, stress, and urgency incontinence in

African women because the number of women seeking care for pelvic floor disorders is significantly lower than those in well-resourced settings. The limited number of prevalence studies, however, suggests that the proportion of women suffering with these problems is comparable to other regions. The reasons for these women failing to seek help have not been properly determined. It may be that women lack the financial resources for a problem that only has an impact on her quality of life. Another possibility is the perception that nothing can be done about the problem and this may be reinforced by the relative lack of training in managing female pelvic floor dysfunction in large parts of Africa. Women on the continent also play an important socioeconomic role in their respective communities and may not prioritize seeking help for quality of life issues such as incontinence or pelvic organ prolapse. It is also important to note that in many parts of Africa, women are not empowered regarding their health and their reproductive health in particular.

Fistula-Related Incontinence

Obstetric fistulas are overwhelmingly the most important problem in female pelvic floor dysfunction in Africa. They are a devastating condition that leave women profoundly stigmatized and isolated from their communities. When one considers the pathophysiological mechanism responsible for the development of an obstetric fistula, the patient experience in the evolution of a fistula is horrifying. Prolonged, neglected obstructed labor will result in the fetal head being wedged into the maternal pelvis, leading to increasing tissue necrosis. Fetal death then occurs and macerates results in softening and eventual passage of the soft, macerated body [9]. If the woman survives this ordeal, the ensuing maternal injuries are often extensive. Many urogynecologists working in well-developed settings will be astounded by the extent of bladder and urethral injuries incurred by many of these women. This often includes either partial or total necrosis of the urethra, total avulsion of the urethra from the bladder, and extensive defects of the bladder itself. In addition to vesicovaginal fistula, many women have severe vaginal scarring and the cervix is often destroyed. They are often amenorrheic due to uterine damage and pituitary necrosis. A study in Nigeria found that 32% of women with fistula also had significant skeletal injuries, including symphyseal separation with gait abnormalities, marginal fractures, bone spurs, and complete obliteration of the symphysis [10].

The United Nations Population Fund in 2003 launched a global campaign to end fistula [11]. Accurate figures of the prevalence of fistula are not available. A recent systematic review by Adler et al. [12] has reported the overall prevalence in sub-Saharan Africa for fistula to be 1.60 per 1000 women of reproductive age. This was calculated from data extrapolated from two studies that included 28,128 participants.

One of the largest studies was a prospective population study of 19,342 women in west Africa [13], and this reported a prevalence for fistulas of 10.3 per 100,000 urban and 123.9 for rural dwelling women. Extrapolating from these data, the authors estimate a prevalence of 33,451 new obstetric fistulas per year for sub-Saharan Africa. Another cross-sectional study [14], this time reporting on data captured in Ethiopia, found a prevalence of 2.2 per 1000 women of reproductive age. They also found that at least 1.5/1000 of women remained untreated. The 2005 Malawi Demographic and Health Survey [15] collected national prevalence data on fistula through a proxy measure of symptoms. After interviewing 11,698 women, a crude rate of 1,557 per 100,000 live births and a lifetime prevalence of 4.7% was calculated.

Sobering demographic data on fistula emerged from a sample of women treated at the renowned Addis Ababa Fistula Hospital between 1983 and 1988 [16]. The mean age was 22 years, 42% were younger than 20 years of age, 52% had been deserted by their husbands, and 21% lived by begging. Furthermore, 30% had delivered without assistance and the average labor had lasted 3.9 days. Kelly and Kwast [17] also reported on a sample of 309 women attending in the Hamlin Bahir Dar Fistula Centre in Ethiopia and found that 82% had travelled at least 700 km for treatment, walking an average of 12 hours, and spending an average of 34 hours on a bus, before arriving at the treatment center.

Wall and colleagues [18] analyzed 899 obstetric fistula patients from Jos, Nigeria, and found that women with fistulas tended to have been married early (often before menarche), to be short (nearly 80% were less than 150cm tall) and small (mean weight less than 44 kg), to be impoverished and poorly educated, and to live in rural areas. Kelly [16] report that more than 50% of women with fistulas had been rejected by their husbands.

Much concern has focused on the impact of genital cutting practices, commonly referred to as “female circumcision” or “female genital mutilation” (FGM) [19] and its relationship to fistulas. About 2 million African girls per year undergo female genital cutting. It is most prevalent in Somalia, Ethiopia, Sierra Leone, Sudan, and Djibouti. Urinary incontinence may occur if there is direct injury to the bladder or urethra. It may also obstruct the vaginal outlet and hence make fistulas more common following delivery. The literature reporting on the role of FGM in the development of fistula and incontinence is thus unclear. Peterman and Johnson [20] could not find a significant relationship in their Demographic and Health Surveys study in Malawi, Rwanda, Uganda, and Ethiopia. Dirie and Lindmark [21] interviewed 290 Somali women between the ages of 18 and 34 who had undergone FGM. The mean age of the cohort was 22 years. Eighty-eight percent of women had undergone excision and infundibulation is 88%, 6.5% clitoridectomy, and 5.5% excision of the clitoral prepuce. Thirteen percent of the women experienced late complications including pain at micturition, dribble incontinence, and poor urine flow.

Various traditional African remedies are also associated with the development of fistulas. The Northern Nigerian practice of “gishri cutting” involves making a series of vaginal incisions with a glass, a blade, or a knife. Between 2% and 13% of women undergoing this gishri procedure will get a fistula [18]. Herbal remedies for various gynecological conditions, which involve the insertion of caustic chemicals vaginally, are also often used by traditional Africa healers [22]. The ensuing vaginal fibrosis and stenosis will occasionally lead to fistula formation.

Fistulas caused by sexual abuse and rape are a particularly troubling phenomenon [23]. Peterman and Johnson [20] used the recent Demographic and Health Surveys in Malawi, Rwanda, Uganda, and Ethiopia to determine the relationship between sexual violence, female genital cutting, and incontinence. Sexual violence was a significant determinant of incontinence in Rwanda and Malawi but not in Uganda. They suggest that elimination of sexual violence will result in up to a 40% reduction of the burden of incontinence. In situations of conflict, refugees and displaced women and girls often have been sexually assaulted. In wartime conditions, sexual violence is a commonly used tactic to intimidate and control. Aid workers have estimated that in war-affected areas, one woman in three is a rape victim, and the majority of new nonobstetric fistula cases are caused by sexual violence.

Fistula reconstructive surgery is complex and usually requires a high level of experience and skill. Most gynecologists, urologists, and general surgeons will not be able to offer this service without extensive training, and therefore, access to surgery varies extensively in sub-Saharan countries. Most women are dependent on the goodwill of itinerant surgeons who offer their services at little or no cost. In 2004, Browning [24] calculated that it will take 400 years to catch up on the backlog of candidates waiting for surgery and a concerted effort to train local physicians in the management of fistula is therefore required. The support of the international community is also mandatory, and this includes increasing involvement from the large organizations involved in continence care, including the International Urogynecological Association and the International Continence Society.

It is important to note that a significant proportion of women remain incontinent following repair of vesicovaginal fistula [24–26]. A group of 150 Ethiopian women was studied using urodynamics by Goh et al. [27], to determine the reasons for ongoing incontinence after repair. In their cohort, 49% had stress and 43% had mixed incontinence. They concluded that the reduced success rates following surgery for fistula may be due to the lack of attention to the other reasons for urinary symptoms and markedly impaired urethral function. This study highlights the importance of increased engagement between the clinicians involved in fistula repair and those with a urogynecology interest.

The main focus of fistula programs in Africa should be on their prevention. An obvious strategy would be to emphasize the establishment of a large number of rural obstetrics facilities on the continent. As far back as 1998, Waaldjik [28] reported that 75,000 new obstetrics hospitals would need to be built to address this problem. Millennium Development Goal (MDG) 5A [29] is to improve maternal health by 2015. Unfortunately sub-Saharan Africa has fallen far below the required reduction in maternal mortality. The aim of having an increase in the number of women delivering with a skilled birth attendant has also not been achieved. MDG 5A also required a significant reduction in teenage pregnancy and increase in access to contraception. It is unfortunate that large parts of Africa will not even come close to achieving the goals of MDG 5A by 2015. A concerted effort at multiple levels will have to be made in the future if obstetric fistulas are to be eradicated on the continent.

Nonfistulous Incontinence

Stress urinary incontinence, overactive bladder, and mixed urinary incontinence have been overshadowed by the profound problem of fistula-related incontinence. However, African doctors will not be able to ignore this problem for much longer. Irwin et al. [30] have predicted a 30.8% increase in the number of women with urinary incontinence in Africa. This increase is primarily attributed to the substantial growth (29.3%) that is predicted within the general population between 2008 and 2018.

One of the challenges in acquiring data in Africa has been the unavailability of validated incontinence questionnaires in the local languages. Fortunately, this is changing and clinicians are now making an attempt to address this need. Juul et al. recently validated the Kings Health Questionnaire in Xhosa and Afrikaans, 2 of the 11 official languages of South Africa [31]. El-Azab and Mascha [32] have made a valuable contribution by validating the UDI-6 and IIQ-7 in Arabic, which is spoken by 178 million Africans living in the north and the horn of the continent. The Arabic IIQ-7 was modified to suit the Egyptian culture. Of note is that they reported a prevalence of 54% for urinary incontinence using the UDI-6. The prevalence of urge, stress, and mixed incontinence were 15%, 15%, and 25%, respectively [33]. An important aspect of quality of life emphasized by this study was that 90% of the subjects stated that the main issue was the inability to pray, due to the presence of urinary soiling. Out of the 1000 Moroccan women older than 18 years sampled by Mikou et al. [34], 271 (27%) reported incontinence in the previous month, with 49% complaining of stress urinary incontinence.

Ojengbede et al. [5] performed one of Africa's largest epidemiological studies on nonfistulous incontinence in Nigeria. In this community survey of 5001 women, the proportion of women who had ever experienced urine leakage was 7.2%, whereas only 2.8% experienced leakage at the time of the survey. The types reported included stress (2.3%), urge (1%), and mixed (0.6%) incontinence. This is significantly lower than the prevalence for all types of incontinence reported in other studies both in Africa and in other parts of the world [35]. The low prevalence of incontinence in Ojenbede's study is most likely due to the fact that 70% of the women were under the age of 50 years. This study also highlights the challenges of epidemiological research in Africa. The authors made use of an interviewer-administered questionnaire, and the authors have suggested that women may have underreported their symptoms due to embarrassment. The questionnaire was also not an internationally recognized and standardized instrument. Okonkwo et al. [36] in another paper, also from Nigeria, reported much higher incontinence rates in 3963 women presenting, with symptoms other than pelvic floor dysfunction, to a gynecology clinic The results revealed that 773 (19.5%) respondents had stress incontinence, while 864 (21.8%) had urge incontinence. An even higher percentage of women had urinary incontinence in another West African study, this time from Ghana [37]. In 200 randomly selected women attending for ultrasound, 62% had at least one symptom of incontinence. A "paper towel" test was used to objectively detect stress urinary incontinence, and 42% had a positive test with 80% of these having at least one symptom of incontinence.

Table 7.1 Results of an Incontinence Survey in South Africa

	Black	**Colored**	**White**
Numbers	411	390	406
Age	41	42	47
Parity	2.9	2.5	1.9
Stress urinary incontinence	9.0	8.2	10.3
Urge incontinence	15.3	12.8	9.9
Urinary urgency	23.4	25.0	15.3
Bothered by symptoms	13.9	12.6	10.6
Has had treatment	9.8	10	11.6

Source: Adapted from Rienhardt G et al., *Int J Urogynecol*, 14, S23, 2003.

There have been a number of studies in South Africa. Bailey et al. [38] evaluated 109 women working in a hospital setting and reported a prevalence of 25% for incontinence, but only 11% of these described it as severe. Another community-based study in South Africa [39] reported a prevalence of 35.4%, with a quarter of these women having sought help for the condition. This study also reported on pelvic floor exercises. Thirty-five percent of the total cohort had some knowledge of pelvic floor exercises with the majority of these women getting this information from the media.

In another South African study, Rienhardt and coworkers [40] interviewed 1207 women in a primary care setting using a questionnaire based on the Leicester MRC incontinence study survey (Table 7.1). This study showed little difference in the incidence of stress urinary incontinence across different age groups and race.

The clinical observation that black women have less stress incontinence than their white counterparts has long been suspected, perhaps on the basis of differences in the quality of connective tissue [41]. This impression has been strengthened recently by work by Laborda et al. [42] and Thiem et al. [43] who demonstrated the presence of an elevated elastin content in the tissue of black women. This issue needs to be clarified by further studies.

The management of incontinence in Africa remains a major challenge. The standard treatment options for incontinence that are available to women in well-resourced settings are not accessible in most parts of Africa. A mid-urethral sling, for example, costs approximately $500, which is often a lot more than the average household income for a middle-class African family. When training doctors working in low-resource settings, it is essential for them to be familiar with cost-effective strategies. Options such as the fascial pubovaginal sling and Burch colposuspension will remain standard treatment options in this region for women with stress incontinence.

PELVIC ORGAN PROLAPSE

For most parts of Africa, there are even fewer epidemiological data on pelvic organ prolapse. In their review on a urogynecology research in Africa, Maki et al. [3] found only 21 papers in PubMed on prolapse from the continent. With the high parity associated with African women, one would expect large numbers of African women to be suffering with this problem. One of the best studies on the epidemiology of pelvic organ prolapse in Africa was the community-based reproductive health survey conducted in Gambia by Scherf et al. [7] In this paper, authors used questionnaires to assess 1067 women for pelvic organ prolapse symptoms. These women were also examined to determine the presence or absence of prolapse. Of note is that the mean parity in this cohort was 6.7. Fourteen percent of the patients had moderate or severe prolapse, warranting surgical intervention. The proportion of these women who actually reported symptoms in the questionnaire, which was administered via a fieldworker, was only 16%. The authors felt that the most likely explanation for the underreporting of symptoms is that women do not interpret what they feel as abnormal, perhaps assuming that a certain amount of discomfort or even pain does not indicate a problem. Zurayk et al. [44] have found that women in developing societies are socialized to endure pain and discomfort particularly if it is related to a problem of the reproductive organs. Walraven et al. [45], in their reproductive morbidity study found that women tend to underreport their symptoms, unless they were related to a genital ulcer or infertility. The issue of underreporting of pelvic floor symptoms and the delay in seeking medical care requires further investigation in Africa.

Another Ghanaian community-based [45] study of 200 women reported a prevalence for pelvic organ prolapse of 12%, with 80% of these women reporting significant symptoms. Only one-third of women with symptoms had sought medical care. The main reason for not having treatment was cost. A hospital-based study of 143 women in Ethiopia [46] found that the patient’s occupation was a significant risk factor for prolapse. They report that 68% of women were employed as rural women farmers and that their day-to-day tasks included assisting in the farmland, marketing, wood and water collection, carrying their babies on their backs, and grinding corn. Many of these women were even expected to perform these tasks during pregnancy and puerperium that may have a detrimental effect on pelvic organ support structures.

Very little data are available on the procedures that are being offered to women with pelvic organ prolapse. However, the data that are available [46,47] would suggest that most surgeons are opting for a native tissue vaginal surgery approach to address the prolapse. Most often this involves a vaginal hysterectomy and colporrhaphy.

FUTURE CONSIDERATIONS

In the next 90 years, the population on the African continent is projected to grow fourfold [48]. This will be associated with significant challenges for a region that has traditionally faced significant poverty and unemployment. The continent has, however, demonstrated encouraging signs of development with economic growth exceeding 4% in 2012 and 2013 [49], despite a global economic recession. Large parts of Africa are rich in natural resources, and there are numerous indicators suggesting rapid growth in the proportion of people with a sizeable disposable income. We can only hope that this will have a significant impact on the obstetric services and reduce the number of fistula on the continent. Economic growth and an improvement in the status of women will also increase the demand for medical services that enhance quality of life. The international urogynecology community therefore has a responsibility to increase training opportunities in the management of women with nonfistula incontinence and pelvic organ prolapse.

Tackling the Stigma of Incontinence

Diane K. Newman

INTRODUCTION

It is estimated that a quarter of a billion people worldwide suffer from urinary incontinence (UI) of varying degrees with the burden of this condition greater in developing countries (Asia, South America, Africa), making it a global health problem. The prevalence of fecal incontinence (FI) is near 10% in the general population [1]. Brown and colleagues [2] reported that one-fifth of mature U.S. women suffer from bothersome leakage of stool in the absence of acute diarrhea illness at least once a year. Despite the considerable impact of UI and FI (referred to as “incontinence”) on quality of life (QoL), many people never seek help for either UI or FI and are thus uncounted [3–6]. There has been extensive research documenting the success of various forms of conservative treatment, but reality is that less than 50% of persons with UI seek help [7,8], and even less inform a health-care provider that they have FI. Many more, especially in less developed countries, do not have help available [8,9]. The psychological consequences of incontinence are well documented, and barriers to seeking help have been frequently identified in the literature. Barriers include embarrassment, social stigma, and the mistaken belief that incontinence is either inevitable, untreatable, or a normal part of aging [10]. Public awareness and community-based continence promotion programs are ways to destigmatize UI and to promote understanding about this widespread condition [8]. This chapter will discuss the stigmatization of UI and FI and provide examples of what is currently being done worldwide to increase awareness and understanding.

THE BASIS OF STIGMA

The word stigma has been defined in different ways including “as a mark of disgrace or reproach” and as “a moral or physical blemish that serves to identify a disease or condition.”

These are negative attributes as they discredit an individual, reduce the person from a whole and usual person to a tainted, discounted one. Gartley’s [11] definition of stigma is the “recognition of difference based on some distinguishing characteristic or ‘mark’ and a consequence of devaluation for the person.” Garcia and colleagues [12] note that persons who are stigmatized are discredited thus reducing the person to a tainted human being. Stigmatization is characterized by chronic social and physical avoidance of a person(s) by other people. The key feature associated with stigma is that often, the stigmatized person and society represent extreme positions of the condition. These definitions and attributes of stigmatization are closely aligned with incontinence. Gartley [13] notes that stigma in health care is a subset of stigmatization in society and is costly for all. Heinz [14] notes that stigma associated with UI signifies something lost or abnormal.

There are several types of stigma (see Table 8.1), and each addresses an aspect of incontinence behavior. Oaten and colleagues [15] proposes that many forms of stigmatization reflect the activation of this disease-avoidance system, which is prone to respond to visible signs and labels that connote disease, irrespective of their accuracy. Joachim and Acorn [16] developed a framework that would explain how people respond to stigmas. They found that the visibility or invisibility of the condition was crucial. If it could be kept invisible (e.g., urine or stool leakage), individuals had options about whether/when to disclose information about their condition. When it was more visible, they had to focus on whether the condition could be hidden. When it could not be concealed, more stigma was likely.

STIGMA AND ITS ASSOCIATION WITH INCONTINENCE

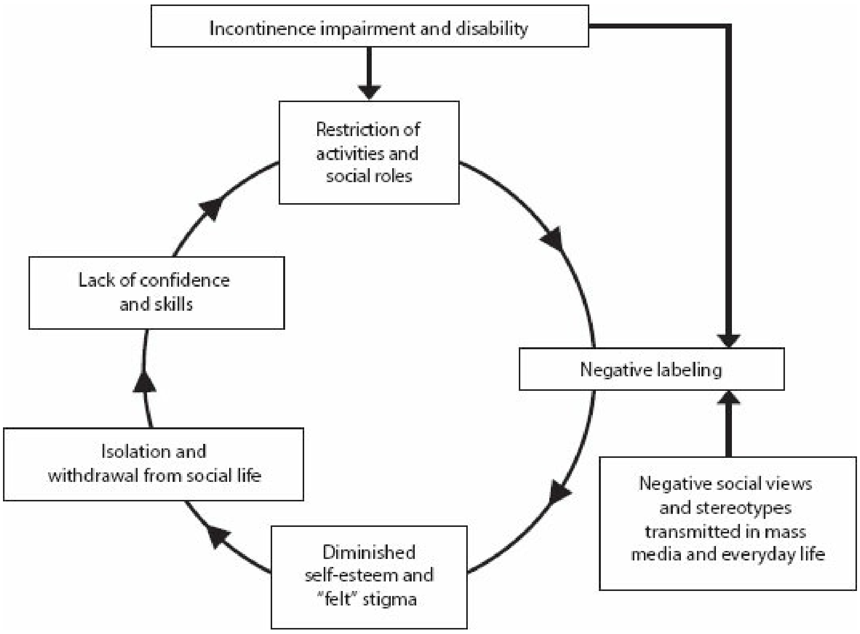
Being stigmatized because of a chronic disabling illness means being responded to differently by the general public [17]. Three strategies are used to manage stigma: avoid hurtful situations, pass as normal, and appropriate a philosophy to help cope with the stigma (Figure 8.1).

The stigma, level of shame, and embarrassment attached to incontinence is higher than that for depression and cancer [18]. This is not surprising as bladder and bowel continence is an adjustment to the social norm, especially in Western cultures, which have developed acceptable rules and behavior for bladder and bowel emptying [19–21]. UI has frequently been linked with incompetence because control and self-restraint is important to notions of adulthood in Western society. Many feel humiliated with their condition and uncomfortable discussing UI with health-care providers [8]. Yuan et al. [22] found that many patients considered UI as shame and their own fault and were unwilling to talk about incontinence with their families, friends, or doctors.

Our society places a significant emphasis on sanitation and personal hygiene [23]. Discussions of personal hygiene and/or elimination are not part of social conversations, especially in Western cultures. During toilet training, children are inoculated with all the cultural norms and expectations concerning elimination of urine and stool [24]. If incontinence occurs in adulthood, persons revive those childhood beliefs and begin to internalize their condition causing a decrease in self-esteem and feelings of shame and of not being "normal" [10]. These barriers are shared by the public as well as by many health-care providers and may contribute to the burden of caregiving [25].

Table 8.1 Types of Stigma

Type	Definition	Behavior related to incontinence
Felt or perceived stigma	Internalize negative perceptions regarding oneself	• Denial of the problem. • Embarrassment resulting in lack of disclosure to family members, friends, or providers. • Feels "dirty," contaminated. • Discomfort with disclosing symptoms. • Concerned about odor.
Self-stigma	Harsh or unjustified beliefs about oneself	• Belief that they are the only person with the problem. • Self-isolation. • Avoids intimacy, feels sexually undesirable. • Mistaken beliefs such as "art of being a women," "part of growing old."
Enacted stigma	Discrimination that takes place at an institution or from a group	• Disgust expressed by others because of odor, frequent trips to the bathroom, etc. • Long-term care staff avoid or ignore UI complaints. • Fear of institutionalization. • Media subtle messages to "keep UI in the closet" or comparisons to "plumbing" that can be fixed.



Incontinence impairment and disability
Restriction of activities and social roles
Negative labeling
Negative social views and stereotypes transmitted in mass media and everyday life
Diminished self-esteem and "felt" stigma
Isolation and withdrawal from social life
Lack of confidence and skills

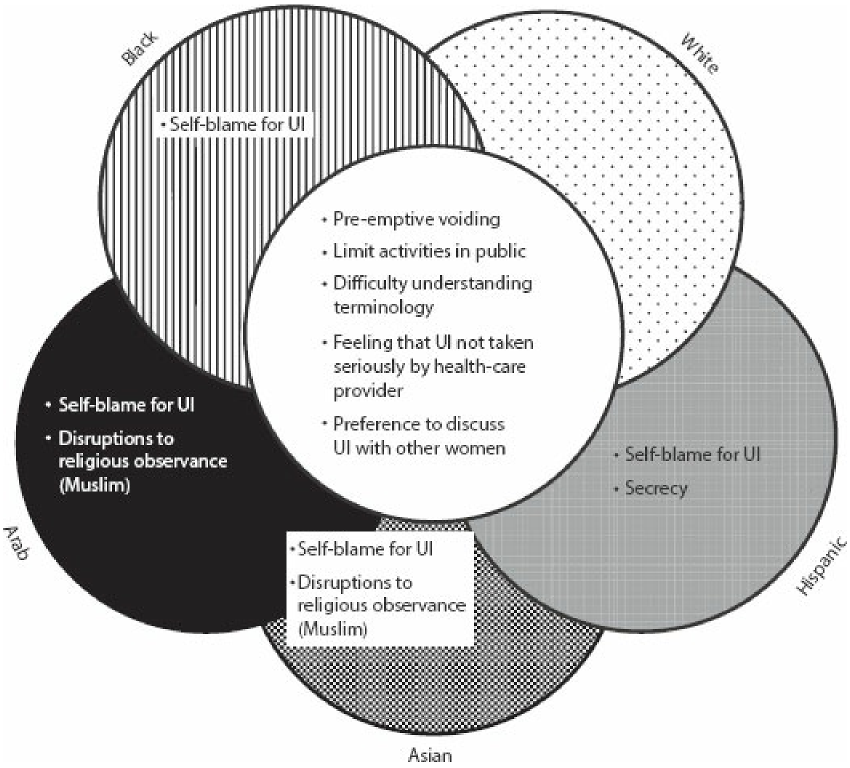
Figure 8.1 Cycle of incontinence stigma: negative feedback between incontinence stigmatization, self-esteem, and participation in social activities.

Avoidance of incontinence is a strategy many use and is a worldwide coping measure. Seshan and Muliira [5] conducted a study by going door to door in Coimbatore, South India, to interview women about the presence of UI and attitudes on the condition. Of the 598 participants recruited in the study, a total of 202 (33.8%) reported that they had UI and 396 (66%) denied having UI. The attitudes of these women about UI were negative whether they experienced the problem or not. More than 80% of all respondents stated they agreed with the following statements:

- Accidental loss of urine is a common problem that every woman faces.
- Women should not go for social events if they have UI.
- There is no treatment available for UI.
- UI cannot be prevented or cured.

The embarrassment associated with UI was evident as 65% of women who reported UI had not revealed their problem to anyone, professional or not. There is no question that the stigma of UI prevents help-seeking in women [26]. Persons with incontinence experience insensitive language and loss of freedom and endure questions of a sensitive nature.

The experience of UI generally included the subthemes of fear, stigmatization, and shame. Siddiqui and colleagues [27] systematically reviewed perceptions regarding UI in women of different racial and ethnic backgrounds. Dominant themes fell into two categories, UI management and UI experience, and were similar across racial/ethnic groups. Women reported a preference for discussing UI with other women, even if this was not a physician. Nonwhite women expressed self-blame and perceived UI as a negative outcome from childbirth or prior sexual experiences. Latina women maintained more secrecy around this issue, even among family members. Figure 8.2 depicts the themes among these women.



Black
• Self-blame for UI
White
• Pre-emptive voiding
• Limit activities in public
• Difficulty understanding terminology
• Feeling that UI not taken seriously by health-care provider
• Preference to discuss UI with other women
• Self-blame for UI
• Disruptions to religious observance (Muslim)
Arab
• Self-blame for UI
• Secrecy
Hispanic
• Self-blame for UI
• Disruptions to religious observance (Muslim)
Asian

Figure 8.2 Similarities and differences in perceptions about urinary incontinence on different ethnic groups.

Similar perceptions are reported by persons who experience fecal or anal incontinence. Olsson and Berterö [28] conducted a qualitative interpretative study based on interviews conducted with five women living with FI. The analysis resulted in four different themes: self-affirmation, guilt and shame, limitations in life, and personal approach. They found that living with FI had a lot in common with living with a stoma, including associated taboo, guilt and shame, and a persistent need for control.

Ignorance and lack of tolerance by and of others is common, leading frequently to anger and withdrawal. Whether the condition is visible or apparent to others (e.g., disfigurement) or concealed (e.g., colostomy or incontinence) does not change the way the person with the condition feels or reacts. The stigma associated with incontinence is similar to the stigma in other conditions and is associated with public ignorance and lack of awareness. The shame, embarrassment, and stigma associated with these conditions pose significant barriers to seeking professional treatment, resulting in many persons who suffer from these conditions living in silence [12,29]. The traditional medical model of care is very much focused at "treatment" but does not empower the sufferer to actually develop strategies to cope with what is often a lifelong condition. The topic of stigma associated with both UI and FI have received scant attention in the research literature despite its associational.

SOCIAL "TABOO" SURROUNDING THE LACK OF BLADDER AND BOWEL CONTROL

Bladder and bowel problems are ignored, they are taboos, subjects not talked about because the truth is too unpleasant for people to acknowledge [30]. Society also ignores the presence of a taboo by refusing to acknowledge or address it; the taboo is stigmatized [31]. It is possible to understand the long-standing stigma surrounding unexpected loss of urine and feces by considering the potential health consequence of incontinence on society [9]. Epidemiological and clinical studies of individuals with incontinence indicate that the condition has a considerable impact on overall QoL and well-being. The inability to control urine or feces is one of the most unpleasant and distressing symptoms a person can experience, causing stigmatization and denial of the condition [12]. Emotional well-being is impaired, probably as a result of social isolation and feelings of stigmatization produced by the incontinence. Society does not know how to respond to persons with incontinence, so avoidance is the norm. This public stigma affects treatment-seeking attitudes through internationalization of messages [32].

STIGMA AND ITS EFFECT ON CARE-SEEKING

A common phenomenon seen in conditions that have greater stigma (and often are less life-threatening) is that they tend to take a much longer time to be reported to a health-care provider (e.g., physician) and even longer to family, friends, and others. Urologic and gastrointestinal symptoms are associated with feelings of stigma, making it challenging for individuals to talk with doctors about their condition [33,34]. To avoid embarrassment, persons with incontinence turn to "self-management" rather than "seeking help" from a doctor or nurse. Unfortunately, factors that promote care-seeking behavior for incontinence issues remain less researched and are complex and multifactorial [8]. With chronic problems like urinary and FI, it is important to understand what triggers the patient to consult a health-care provider [35]. Older adults may be keen to seek help if they are concerned that a health issue such as how incontinence impacts on their ability to remain independent and living in the community [21]. In certain parts of the world, the gender of the person with incontinence may be a factor in help-seeking behavior and the gender of the health-care provider may be a barrier. A known barrier is terminology for incontinence as how patients relate their condition may not match health-care professional's medical assessment. In an Internet-based survey of mature women who reported FI, they preferred the term "accidental bowel leakage" (n = 667, 71.1%) as opposed to "bowel incontinence" (n = 211, 22.5%) and FI (n = 60, 6.4%) [2].

Barriers to seeking help for continence issues that have been frequently identified in the literature include embarrassment, social stigma, and the mistaken belief that incontinence is inevitable, untreatable, and/or a normal part of aging. The authors of a Swedish study suspected that lack of knowledge, worries about different procedures, and negative expectations may be important factors in reducing the desire to seek treatment among even those most severely affected [36]. Embarrassment and fear of humiliation have been identified as the major factors influencing reluctance to seek help among women with long-term UI [37]. Among women affected by UI in the UAE, reasons for not seeking help included embarrassment (38.2%), choice of self-treatment because of low expectations from medical care (38.2%), and assuming that UI is normal (23.3%) [38]. Among women with gynecological cancers who experience concomitant LUT, failure to seek help for the latter symptoms has been attributed to a perception that the LUTS were not serious enough symptoms to warrant attention and lack of awareness of treatment options [39].

The Boston Area Community Health population-based random epidemiological survey of urologic symptoms (n = 5503) indicated that the stigma of UI also includes other lower urinary tract symptoms (LUTS) [34]. Overactive bladder (OAB) symptoms of urgency and frequency were linked to social interruption, loss of socially expected control of the body, not understanding the nature of the bladder problem, and the need to mix private behavior and public space. The stigma of OAB and UI was correlated to whether the problem was perceptible (i.e., odor or observation of trips to the bathroom or soiled clothes) or concealed. Men reported feeling stigmatized for being seen making frequent trips to the bathroom and feared being viewed as impotent. Women feared being stigmatized based on having an unclean body and a compromised social identity. Like others, Hispanic individuals wanted to keep urinary symptoms a secret from others.

Patel et al. [40] found that many patients had a significant emotional component to their experience of FI and that knowledge about the terms used to describe the condition was often limited.

INCONTINENCE, ATTITUDES, AND BELIEFS

The way people react to a person with incontinence is influenced by many factors. The further the person is connected from the sufferer, the more negative attitudes become. As the condition becomes more severe, the more obvious it becomes to others, and often, therefore, the more the person is likely to be stigmatized [12,21]. In addition, attitudes and reactions of both the person with incontinence and those in society who interact with that person may vary according to the age of the person. At the extreme is the newborn child, where incontinence is regarded as a norm, through to childhood bedwetting, all the way to a frail old person in a nursing home. Depending on the age, sex, and social situation of the person, the reaction may well be different.

It is important to understand how attitudes and stigma changed for these conditions. An important component is breaking the cycle of public and personal ignorance through education and public awareness programs [8,29]. For this to be successful, there needs to be a partnership between health-care professionals, governments, and industry groups with a vested interest to work together to break the cycle of ignorance and negative attitude. Central to this is the availability of funds, either in allocated dollars or “in kind” (e.g., access to advertisements), which represents an ongoing funding source. A group of experts [9] conducted a systematic review of existing evidence, collated qualitative data, and used expert consensus to develop an internationally applicable service specification for continence care around the world. This service can be tackled locally and internationally in order to raise awareness of incontinence, bring a greater opportunity to incontinence management, and improve the plight of hundreds of millions of people around the world.

The good news about stigma is that individuals and society as a whole continues to change its views on what is or is not a stigmatizing condition. One reason is technology as consumers now have immediate access to information about incontinence via the Internet and social media (e.g., YouTube). In light of the reluctance of those affected by stigmatized illnesses such as incontinence to seek treatment or to ask health-care professionals for information, the Internet may prove to be a useful tool for patient education, public health outreach, and improving QoL in those with incontinence [41]. In a national survey of Internet users in the United States, Berger and colleagues [42] found a trend among people with a stigmatized illness such as UI to more likely report that using the Internet increased their health-care utilization and communication with a health-care provider.

ROLE OF NATIONAL ORGANIZATIONS

As previously mentioned, the stigma associated with incontinence is similar to other conditions and is associated with public ignorance and lack of awareness. An important component is breaking the cycle of public and personal ignorance through education and public awareness programs. As the stigma associated with incontinence is similar to other conditions and is associated with public ignorance and lack of awareness, educating the public will increase their awareness of the condition. Therefore, it is important to understand how attitudes and stigma have changed for these conditions. There have been some advances in breaking the cycle of public and personal ignorance through education and public awareness programs [43]. Patient advocacy organizations for UI have been formed worldwide to promote awareness (www.icsoffice.org).

Continence promotion involves informing and educating the public that incontinence is not inevitable or shameful, but is treatable or at least manageable [8]. The International Continence Society, a professional organization, has supported the work of organizations that promote incontinence awareness and education, and promotion. Although the ratio between affected patient populations and continence national organization funding has not been formally studied, anecdotal information suggests that continence promotion is among the most difficult of medical problems for which to obtain funding. In view of all these challenges, the proliferation of new national continence organizations, especially in Asia and South America, is a validation of both the need for continence promotion and the dedication of those who have recognized and are addressing this need.

SUMMARY

In order to improve health care for those men and women with incontinence, the social stigma must be removed, public education about resources and treatment must be increased, and health-care professionals need to be trained in incontinence management. The good news is that there is a growing international awareness about the need to "destigmatize" incontinence by promoting awareness through partnerships of health-care professionals, governments, and industry. This process must continue in order for incontinence to be removed from the list of conditions associated with stigma so that people can and will seek help.

Natural History and Prevention of Urinary Incontinence and Urogenital Prolapse

C. K. Madhu, R. Trochez, and Robert M. Freeman

INTRODUCTION

There are few studies that have prospectively evaluated the natural history of urinary incontinence (UI), pelvic organ prolapse (POP), and fecal incontinence (FI) in women who have not undergone treatment. Epidemiological studies are described in Chapters 2 through 7. A hypothesis for the natural history is presented with possible implications for preventative strategies.

The chapter is organized under the following headings:

1. Natural History Urinary Incontinence
2. Natural History of Pelvic Organ Prolapse
3. Natural History of Fecal Incontinence
4. Risk Groups and Preventative Measures
5. Prevention of Urinary Incontinence and Prolapse following Gynecological Surgery

NATURAL HISTORY OF UI

Hypothesis for the Genesis of SUI

The processes during pregnancy and childbirth and factors like age, body mass index (BMI), chronic cough, and genetic factors seem to have an effect on prevalent UI and POP [1]. During pregnancy the endopelvic fascial attachments of the bladder neck and distal sphincter are weakened possibly due to hormonal influences [2]. Progesterone reduces urethral closure pressures and produces connective changes [3,4] that probably contribute to the high incidence of any antenatal incontinence. In most cases, however, incontinence *improves* after delivery [5]. Why stress urinary incontinence (SUI) should persist postpartum in some women is unclear, but vaginal delivery is implicated. If the endopelvic fascial attachments and sphincter function are not damaged at delivery, then the changes seen antenatally are likely to revert to the *nonpregnant* state with the return of urethral function and continence. However, if these structures are damaged or are inherently weak in the *nonpregnant* state, then recovery might not arise. Support for this hypothesis comes from studies suggesting the presence of a constitutional factor, e.g., weak connective tissue/fascia in women with SUI [6,7]. For example, there is a known association between connective tissue disorders and UI and POP, e.g., in Marfans and Ehlers–Danlos syndromes [8]. Also, in women with POP, an association with joint hypermobility has been demonstrated suggesting a possible underlying connective tissue weakness [9]. Should such individuals suffer pelvic floor trauma at delivery, then recovery might not be complete resulting in postpartum SUI. This, along with further deliveries, aging, menopause, and muscle weakness, seems to increase the risk of long-term incontinence [10]. Further support for the hypothesis comes from the growing volume of evidence suggesting that *antenatal SUI* and, in particular, incontinence *before* a first pregnancy are high risk factors for the development of incontinence in later years [11–13].

Natural History of UI

The association between SUI and parity is well known, and, based on the available evidence, the following hypothesis regarding the genesis and natural history can be made (Figure 9.1).

A recently published large prospective longitudinal study with 16 years follow-up of over a thousand women found considerable rates of both incidence and remission of UI, overactive bladder (OAB), and other lower urinary tract symptoms (LUTS) [14]. They reported cumulative incidences of UI and urgency/OAB of 21% and 20%, respectively, with corresponding regressions of 34% and 43%, respectively. However, regression was more frequent in women with mild symptoms, suggesting that clinically relevant UI infrequently improves spontaneously. A systematic review of longitudinal studies of OAB and UI suggests that there is a dynamic progression of symptom severity in OAB, with 28% of women progressing from OAB dry to wet over 16 years, and that symptoms persist over a long period of time [15]. In a study of women reassessed 6 years after childbirth [13], there was a rate of new-onset incontinence of approximately 30% in women who had been continent at 3 months postpartum. However, in 27% who were *incontinent* at 3 months, there was spontaneous remission at 6 years. Of particular interest were those women who were incontinent *prior* to pregnancy; there was a markedly increased risk for leakage at 6 years. These interesting findings suggest that there are women at risk of incontinence, while in others there is spontaneous remission. Identification of such individuals might help in prevention of SUI (and POP) if they can be identified at an early stage (see section “Childbirth”).

Based on data from a systematic review, during the first 3 months postpartum, the pooled prevalence of any postpartum incontinence is 33%, with longitudinal studies showing small changes in prevalence in the first year after childbirth [5]. A study at 3 months postpartum showed nearly one-third of women (29%) had new-onset UI [16]. The same authors showed that at 6 years following the index childbirth, the prevalence of persistent UI was 24% [17]. Another study followed 526 women following childbirth and showed that a prevalence of UI was 11.3% at 6 weeks postpartum and this did not change at 1-year follow-up [18]. In another study (from Australia) at 4–18 months following the women’s first childbirth, 44% of them reported UI and 25% had persistent UI, and majority of these women were symptomatic during pregnancy [19].

Remission of UI

UI can be considered as a dynamic condition. A 5-year longitudinal study of women less than 65 years with a baseline prevalence rate of UI of 23.6% (27.5% at 5 years) showed a mean annual incidence rate of incontinence of 2.9% and a mean annual remission rate of 5.9% [20]. A 4-year longitudinal study of women aged less than 50 years showed a mean annual incidence and remission rates of UI of 4% [21]. Another longitudinal study over 6.5 years showed a mean annual remission rate of 2.9%, and more than half of women in this study with a mild form of UI at baseline had full remission [22]. A larger 2-year study of 64,650 women aged 36–55 years showed complete remission in 13.9% of women with incontinence at baseline [23]. A 2-year study of noninstitutionalized women over 60 years showed a 1-year remission rate of 12% [24].

A study followed 2025 women aged over 65 years for 6 years (baseline prevalence of urgency incontinence was 36.3%, and of stress incontinence it was 40.3%) [25]. This study showed for urgency incontinence, the 3-year incidence and remission rates between the third and sixth years were 28.5% and 22.1%, respectively [25]. For stress incontinence, the 3-year incidence and remission rates between years 3 and 6 were 28.6% and 25.1%, respectively [25].

A longitudinal Swedish population-based study of over 100 women from 1991 to 2007 showed incidence and remission rates of 21% and 34%, respectively [14].

NATURAL HISTORY OF POP

There is limited knowledge on the natural history of POP. The reported incidence for cystocele is around 9 per 100 woman-years, 6 per 100 woman-years for rectocele, and 1.5 per 100 woman-years for uterine prolapse [26].

A 4-year observational study [27] in postmenopausal women showed an overall 1- and 3-year prolapse incidence of 26% and 40%, respectively. This study [27] also showed a 1- and 3-year resolution risk of 21% and 19%, respectively. The study also showed that over 3 years, the maximum vaginal descent increased by at least 2 cm in 11% of the women and decreased by at least 2 cm in 2.7%, with obesity and grand multiparty increasing the risk of vaginal descent progression [27].

The ProLong study, which was a longitudinal study of women (most women were asymptomatic for symptoms of POP) following childbirth, showed a 24% objective POP rate (20% of the study group) at 12 years following the index birth [13]. The SWEPOP (Swedish Pregnancy, Obesity and Pelvic Floor) study showed a 12.8% prevalence of symptomatic POP at 20 years following one childbirth [28].

As with SUI, alterations in pelvic organ support leading to prolapse might occur before delivery. Previously published prevalence studies, which might have been helpful in identifying the natural history of POP, have been hampered by selection bias (e.g., hospital-based populations in developed countries). For example, in such groups, 30%–50% of women seen for other gynecological problems have signs of POP [29,30], but most will be asymptomatic. In older age groups (>70 years), many are symptomatic and approximately 11% will undergo surgery, but there are few data on the numbers treated conservatively, e.g., with pessaries [31].

The natural history of untreated POP has been assessed in menopausal women as part of the estrogen, progestin trial of the Women's Health Initiative (University of California) [26]. Annual pelvic examinations for POP were performed on 412 women (mean 5.7 years) using a (nonvalidated) classification system. At baseline 31.8% had POP. The annual incidences of new-onset POP were 9, 5, and 7 per 100 woman-years for anterior vaginal wall prolapse, posterior vaginal wall prolapse, and uterine prolapse, respectively. Of interest were the rates of progression and regression. For *progression*, the rates were 9.5, 13.5, and 1.9 per 100 woman-years, respectively. Corresponding figures for *spontaneous regression*, especially Grade 1 POP, were 23.5, 22, and 48, suggesting that spontaneous regression is common. Only 3 women (0.7%) required surgery. These findings have been supported by a recent study [32] of 64 women with POP who chose no treatment (observation only) and were followed up with sequential POP-Q examinations (median follow-up 16 months; range 6–91 months). The majority (78%) demonstrated no change in the leading edge of the prolapse between the first and the last visit, following which 63% still continued observation [32]. These data suggest that the clinical sign of POP is common and that spontaneous regression occurs in many cases. The symptom of vaginal bulge is specific to prolapse, and the leading edge at or beyond the hymenal remnants helps define symptomatic POP [33,34]. Treatment might be unnecessary unless the symptoms are bothersome.

In developing countries, untreated POP might be more prevalent. For example, in rural Gambia an epidemiological study showed a prevalence of 46%. Only 8 of 152 with "severe POP" (i.e., subjective and objective) accepted the offer of treatment [35]. There are no data on the outcome for these untreated women. If severe and left untreated, POP can sometimes result in obstructed voiding and recurrent urinary infection. This could progress to obstruction of the upper tracts and renal failure. In a small case series of women with untreated severe POP (i.e., beyond the introitus), all had evidence of bilateral upper tract dilatation, and three had obstructive renal failure. Treatment of POP resolved the renal failure in all but one patient [24]. These findings highlight the need for prevention of upper tract changes by early treatment of advanced POP. Trauma to the cervix and vaginal skin might increase the risk of neoplasia in women with severe POP. However, there are few prospective studies to assess the risk.

NATURAL HISTORY OF FECAL INCONTINENCE

The prevalence of FI at 3-months postpartum was 9.6% in one study [36]. The authors from the same study group showed a 3.6% prevalence of persistent fecal incontinence at 6 years following childbirth (90% of these women were asymptomatic before their first birth) [37]. At 12 years follow-up, 43% of women who complained of FI at 3 months complained of persistent FI (overall prevalence rate of FI was 6%) [38]. There are few data on the prevalence of anal incontinence, which includes flatus incontinence, but it is likely to be much higher than FI alone.

RISK GROUPS AND PREVENTATIVE MEASURES

Ideally, the aim of healthcare is prevention rather than cure. Prevention can be classified as *primary* (interventions in asymptomatic individuals to reduce known risk factors for the development of a disease) or *secondary* (to detect symptoms at an early stage and to intervene to stop further development or to improve the prognosis of the condition). To stop recurrence of an illness or preventing it becoming chronic is *tertiary* prevention. In urogynecology, there is a paucity of large prospective trials to assess the impact of prevention on UI and POP.

There are known predisposing factors such as age, obesity, family history, parity/vaginal childbirth, and surgery. Identification of individuals at risk might help with implementing preventative measures.

Risk Groups

Age

POP is a common condition in older women, and advancing age has a strong correlation with the prevalence prolapse [39,40]. With advancing age, a progressive and age-dependent decrease of the density of striated muscle cells can be observed in the rhabdosphincter (due to apoptosis), which may contribute to UI [41]. Although the prevalence of incontinence is increased in the elderly, the two do not necessarily have a cause-and-effect relationship; other pathological processes associated with aging might be responsible. Resnick has created the mnemonic “DIAPPERS” to describe these: *D*elirium, *I*nfection, *A*trophic change, *P*harmacological, *P*sychological, *E*xcess urine output, *R*estricted mobility, and *S*tool impaction [42]. There is a known association between constipation and POP [43], and attention to regular bowel habit, avoiding straining, a high-fiber diet and, if necessary, laxatives might have a positive effect on prevention. Likewise, management of other risk factors such as chronic cough, smoking, and adjusting medication that has an adverse effect on the bladder could help incontinence (e.g., diuretics, calcium channel antagonists [that can cause polyuria], nonsteroidal anti-inflammatory drugs [that can lead to fluid retention], ACE inhibitors [leading to chronic cough], and sedatives) [44]. Regular toileting, easy access to toilets, restricting fluids (especially caffeine), and prevention of urinary tract infection, e.g., with cranberry juice or vitamin C, might also be effective in the prevention of incontinence in the elderly [44].

Menopause and Hormone Replacement Therapy

There is a definite aging process in the lower urinary tract, resulting in atrophic change and poor urethral function. Hormone replacement therapy (HRT) should in theory prevent LUTS. A recent Cochrane review concluded that local estrogen treatment for incontinence may improve or cure it; however, systemic hormone replacement therapy (HRT), using conjugated equine estrogen, might make incontinence worse [45]. There is limited evidence from randomized controlled trials (RCTs) regarding the use of estrogens for the prevention and management of POP [46].

Urgency

Urgency is a distressing symptom for the older patient with restricted mobility, causing panic and anxiety on the sensation of bladder fullness. There is a strong association between mobility impairment and urgency urinary incontinence (UUI), which is proportional to the severity of UUI [47]. Often, patients void more frequently to prevent urgency incontinence, which can have the opposite effect, by reducing bladder capacity and worsening the symptoms.

Strategies such as explanation, bladder retraining, pelvic floor exercises, easy access to toilets, and the use of bedside commodes might prevent urgency developing into UUI and could also prevent falls. There is evidence that patients with urgency incontinence (more than once a week) are at increased risk of falls and bone fracture than in those without [48]. These might be preventable.

Obesity

Obesity is common in women with UI and POP. When defined as "more than 20% above average weight for height and age," obesity has been shown to be more common in patients with urinary stress incontinence (USI) and detrusor overactivity (DO) than in the asymptomatic population [49]. Increasing BMI is associated with progression of POP for all three compartments, but weight loss was not associated a significant regression of POP, suggesting an irreversible damage to the pelvic floor with obesity [50]. Obesity is also a risk factor for vaginal vault prolapse after hysterectomy [51]. In pregnancy, an increased BMI has been shown to be an important risk factor for persistent UI postpartum [52,53]. Obesity is strongly associated with UI and the odds of UI increases by 1.6 for every 5-unit rise in BMI [54]. In theory weight loss should be preventative. However, studies are often hampered by the failure of subjects to lose weight. One study in morbidly obese women undergoing surgically induced weight loss showed subjective and urodynamic improvement in incontinence 1 year after surgery [55]. In a larger case series of women (BMI > 30) with UI undergoing weight loss, reduced incontinence loss and improved quality of life have been demonstrated in women losing more than 5% body weight [56]. A randomized trial in 338 overweight and obese women found that a mean weight loss of 8% in the intervention group (vs. 1.6% in controls) led to a significant decrease in weekly episodes of incontinence (47% vs. 28%) [57]. A recent systematic review and meta-analysis of studies on weight loss in UI including 2352 women showed that nonsurgical weight loss can improve UI and should be considered part of the standard practice in the management of UI in overweight women [58].

Familial and Genetic Factors

Identification of risk groups is important and family history might be relevant. It has been shown that daughters of women with UI are more likely to develop incontinence themselves [7,59]. A genetic predisposition to abnormal extracellular matrix remodeling, influenced by reproductive hormones, trauma, mechanical stress, and aging could alter normal tissue architecture and mechanical properties leading to SUI and POP [60]. Studies also suggest increased collagenolysis due to genetic polymorphisms playing a key role in extracellular protein turnover, resulting in decreased collagen and development of POP and SUI [61]. A linkage to chromosome 9 has also been demonstrated in families with POP and SUI [62]. A large twin registry study from Sweden concluded that genetic effects do contribute to the occurrence of SUI and POP, but there was a substantial effect of environmental factors providing some hope for preventative strategies [63]. A small study in four pairs of postmenopausal identical twins with different parity status, i.e., nulliparous/parous for each set of twins, found identical continence status in all four pairs, and a difference greater than one stage on the Pelvic Organ Prolapse Quantification (POPQ) assessment in only one set of twins [64], which seems to support a genetic predisposition for both UI and POP rather than parity. Racial differences have also been demonstrated, with white Caucasian women having an increased risk of SUI [65,66] and POP [39] compared to African American women. Also childhood symptoms, e.g., nocturnal enuresis and OAB might predispose to incontinence in adulthood [67]. Identifying and treating these children, e.g., by pelvic floor muscle training (PFMT), might help to prevent symptoms in adulthood.

Childbirth

Vaginal birth probably has an important role in the pathogenesis of pelvic floor dysfunction. However, not all women develop pelvic floor problems following vaginal birth, suggesting that identifying "at-risk" groups might provide an opportunity for prevention [68]. Primigravidae with excessive bladder-neck mobility antenatally (a possible marker for weak pelvic floor collagen) appear to be at higher risk of postpartum stress incontinence [69], itself a risk factor for long-term incontinence [10]. Antenatal and prepregnancy incontinence [11,13] family history of incontinence in pregnancy, obesity [53], and persistent postnatal incontinence [70] also appear to be important risk factors. Age at childbirth, BMI, and maternal height are also known risk factors that increase the risk of UI following childbirth [28]. Levator ani muscle injuries that occur in 13%–36% of women who have a vaginal delivery is associated with the development of pelvic floor dysfunction including SUI, POP, and obstetric anal sphincter injuries (OASIS) [71,72]. Prolonged second-stage labor is also associated with increased likelihood of postpartum incontinence in women who had a spontaneous vaginal birth (adj OR = 1.9) or operative vaginal birth (adj OR = 1.7) [73]. This might be related to pudendal nerve injury [74]. Such nerve damage is seen in patients with USI [75], and it has therefore been assumed that vaginal delivery alone is responsible for subsequent USI and POP. However, this assumption might not be correct; pregnancy itself might also be responsible [76]. For example, nulliparous women with USI appear to have weak pelvic floor collagen [6], and vaginal delivery in these women might increase the risk of SUI and POP if/when they become pregnant.

BMI and maternal height are other risk factors with POP. Symptomatic POP have been shown to increase by 3% for every unit increase in current BMI. Short stature women, e.g., height ≤ 160 cm who deliver a baby ≥4000 g, have been shown to have a doubled prevalence of symptomatic POP 20 years following one vaginal childbirth [28].

Identifying women at risk before or early in a first pregnancy might enable preventative measures to be introduced.

Prevention

Cesarean Section

Identification of risk groups might help with prevention, but what this intervention should be is a matter of debate. While elective cesarean section might prevent neuromuscular damage and postpartum SUI [77], this latter finding is not consistent with incidences of SUI of up to 16% in women delivering exclusively by cesarean section being reported [78,79]. However, a 12-year longitudinal study showed that such women were less likely to have UI than those who only had spontaneous vaginal births (OR = 0.46), but not if they had a combination of cesarean and spontaneous vaginal births (OR = 1.14) [80].

Patients delivered exclusively by cesarean section have a significantly reduced risk of objectively demonstrable POP, 12 years after delivery [13] and symptomatic POP by 20 years after childbirth [28]. After two decades after one vaginal childbirth, there is a 67% increased risk of UI and UI > 10 years increased by 275% compared to cesarean section [81]. This study indicates that 8–9 cesarean sections are need to prevent one case of UI [81]. The numbers needed to treat (NNT) in women who are of short stature with a baby >4 kg is 4 for SUI and 6 for POP (Gyhagen M, personal communication).

A review also concluded that short-term occurrence of any degree of postpartum SUI is reduced with cesarean section; severe symptoms are equivalent by mode of birth [82]. A prospective study showed a significantly increased risk of surgery for SUI and POP 26 years after vaginal childbirths compared to cesarean deliveries [83]. Results from these studies provide evidence for patient counseling and careful planning of mode of delivery to prevent pelvic floor dysfunction. Various models for scoring risk factors have been proposed and are being validated to provide estimates of postpartum pelvic floor pathologies to facilitate decision making and prevention of pelvic floor trauma [84,85].

PFMT

PFMT might be a less invasive form of prevention. For example, in primigravidae with antenatal bladder-neck mobility [69], antenatal PFMT has shown a reduced incidence of postpartum SUI compared with untreated controls [52]. Similar results have been seen in “unselected” primigravidae [86,87]. Postpartum PFMT also seems to be preventative both in the short [88,89] and medium term [90]. A Cochrane review with 22 studies involving over 8000 patients found evidence that PFMT can prevent UI in pregnancy (relative risk [RR] 0.71, 95% confidence interval [CI]: 0.54–0.95) and postpartum (RR 0.60, 95% CI: 0.35–1.03). It seemed that the more intensive the program, the greater the treatment effect [86]. However, the level of intervention, i.e., the PFMT regime, varied greatly in the studies, and it remains unclear whether PFMT should be targeted to women at risk, i.e., primiparous women and women with large babies and forceps deliveries, or should be a population-based intervention. Recent RCTs however failed to show any benefit of postpartum PFMT on POP [91] or UI [92].

Longer-term studies with 6 and 8 years follow-up [93,94] and one review [95] have shown that the initial beneficial effect does not persist, probably due to poor compliance. However, the incontinence in those women was not severe enough to require surgery. As PFMT antenatally and postnatally can be preventative in the short and medium term, Cesarean section might not be necessary except possibly for those women with severe incontinence before and/or during the first pregnancy [10,12] or in those with early-stage symptomatic prolapse.

Can Changing the Management of Labor Help in Prevention of SUI?

This is unlikely as the exact role of obstetric factors in the genesis of postpartum SUI is unclear. For example, there is conflicting evidence regarding prolonged second stage of labor, birth weight, epidural, episiotomy, and mode of delivery. A Cochrane review has shown an increased association of maternal perineal trauma with forceps delivery [96]. The review also suggested a significantly more third- or fourth-degree tears (with or without episiotomy), vaginal trauma, and flatus incontinence with forceps [96]. A study has suggested that the incidence and severity of SUI 1 year after forceps delivery was greater than that after spontaneous or vacuum/ventouse delivery [97]. Forceps and vacuum extraction have different benefits and risks, and the choice of instrument should be based on clinical circumstances and the level of skill of the operator (RCOG Green-top Guidance no. 26, 2011).

Episiotomy

In a Cochrane review, restrictive episiotomy compared with routine use, resulted in less severe perineal trauma, less suturing (RR = 0.71), and fewer healing complications, but with more anterior perineal trauma. There was no difference in UI or several pain measures [98]. However, as with all studies assessing episiotomy, the technique and angle are poorly described (see later).

It would appear that prevention by changing obstetric practice is not possible with the current state of knowledge. However, it might be worthwhile considering earlier delivery (by cesarean section) in short stature primigravidae who have obstructed labor before full dilatation to prevent pelvic floor injury [28]. This might be preferable to prolonged augmentation of labor and the risk of instrumental delivery (see OASIS in the following text).

Prevention of OASIS and FI

OASIS is the most important risk factor for anal incontinence that affects young women [99]. Nearly one-third of primiparous women (29.2%) have occult OASIS following vaginal childbirth (high with assisted vaginal delivery, ventouse less traumatic than forceps) [100]. An ultrasound study reported OASIS in 27.9% of women after their first childbirth, which was not recognized clinically after delivery [101]. Despite repair, 30%–50% of affected women suffer from anal incontinence [102–104], and 40% will opt for a future elective cesarean section to avoid worsening of symptoms from a further vaginal birth [105,106].

A recent study [107] of data from the English Hospital Episodes Statistics (HES) involving over 1 million women who delivered vaginally between the years 2000 and 2012 found that the rate of reported third- or fourth-degree perineal tears tripled from 1.8% to 5.9% during the study period. The rate of episiotomy varied between 30% and 36%. An increasing proportion of ventouse deliveries (from 67.8% to 78.6%) and noninstrumental deliveries (from 15.1% to 19.1%) were assisted by an episiotomy. A higher risk of third- or fourth-degree perineal tears was associated with a maternal age above 25 years; instrumental delivery (forceps and ventouse), especially without episiotomy; Asian ethnicity; a more affluent socioeconomic status; higher birth weight; and shoulder dystocia. The authors concluded that changes in risk factors were unlikely explanations for the observed increase and that this was likely due to better training and recognition. Episiotomy is associated with the lowest risk of OASIS (see the following text).

Detection of OASIS

In women with recognized OASIS/third-degree tears, 85% of them have been shown to have residual sphincter damage despite repair at delivery, with 50% being symptomatic [108]. Many remain unrecognized with one-third of women having an undetected OASI after their first delivery [109]. It is important that obstetricians and midwives are adequately trained in the identification and treatment of OASI as this might help in prevention of FI. Appropriate methods of defect repair are also important. For example, the "overlap repair" for complete tears seems to be associated with a lower incidence of fecal urgency and deterioration of anal incontinence symptoms compared with "end-to-end" repair [110]. Training is therefore recommended. Identification and repair of OASIS might be important in the prevention of long-term FI. This is ongoing via excellent courses run throughout the world (Sultan A and Thakar R, personal communication).

Obstetric Management

Episiotomy might prevent OASIS. For example, fewer third- and fourth-degree tears have been seen following mediolateral episiotomy [111,112], whereas the risk is increased by midline episiotomy [113]. The latter should probably be abandoned due to the high risk of OASIS. HES data in England have shown that episiotomy is associated with the lowest rate of OASIS [107]. A recently published study has confirmed this finding and shown that the prevalence of FI was lower after vaginal delivery with an episiotomy and similar to that after cesarean section [114].

One possible reason for the discrepancy in the literature is that many episiotomies are performed at different angles, closer to the midline resulting in an increased risk of OASIS. Standard obstetrics textbooks state that a mediolateral episiotomy should be performed at an angle of at least 40°, with most suggesting an angle of between 45° and 60°. However, two studies found that most doctors and midwives perform mediolateral episiotomies at a much lesser angulation [115,116]. These findings were confirmed by another study [117], which in addition demonstrated that the risk of OASI decreased significantly from 9.7% in women who had episiotomies at less than 25%–0.05% in women whose episiotomies exceeded 45°. The authors estimated a 50% relative risk reduction of OASIS for every 6° away from the midline that an episiotomy was performed. Instruments to accurately cut a 45°–60° episiotomy are now available [118].

The management of the perineum in the second stage of labor seems to be an important factor in the incidence of OASIS. There is some evidence that the lack of perineal protection ("hands off/poised") has become increasingly prevalent [119] and that this may play a role in the rising incidence of OASIS [107]. Studies have shown a lower OASIS rate with use of active perineal support along with episiotomy [102,120]. A recent Cochrane review, however, showed no differences in the OASIS rates with or without perineal support, but showed reduced perineal trauma with warm compresses on the perineum [121]. However, description of the methods of perineal support was poor and OASIS was not the primary outcome in the studies reviewed by Cochrane.

A recent Cochrane review also failed to demonstrate any benefit of cesarean section in the prevention of anal incontinence and recommended that preservation of anal continence should not be used as a criterion for choosing elective primary cesarean delivery [122]. However, a recently published large cohort study has shown an increased prevalence of FI in primiparous women at 20 years after one vaginal birth compared to cesarean section [114].

Forceps and Ventouse in OASIS

Use of the ventouse rather than forceps might help in prevention. While it has been claimed that both are risk factors for OASIS [123], other data suggest that ventouse is associated with fewer OASIS compared with forceps [124]. In an RCT of ventouse versus forceps delivery, there was a significant reduction in the incidence of third- and fourth-degree tears in the ventouse group [125].

HES data show that forceps without episiotomy has the highest rate of OASIS [107]. However, it might not be the particular instrument that is important, but the indications for the assisted delivery (e.g., prolonged labor), large baby [67], occipitoposterior position [126], short maternal stature [28] are known risk factors for pelvic floor trauma and OASI. These factors are out with the obstetrician's control. Nonetheless, awareness might help in the prevention, e.g., by performing an elective 45° episiotomy or if there are other obstetric indications, e.g., obstructed labor in a woman at risk and delivery by cesarean section.

Subsequent Deliveries in the Prevention of OASIS

Two prospective studies have shown that in primiparous women with persistent FI, the risk of deterioration appears to increase after the second vaginal delivery [103,127]. For these women, secondary prevention might be achieved by elective cesarean section. Large retrospective studies using an anatomical rather than a physiological outcome, i.e., recurrence of OASIS instead of anal incontinence, have also shown that there is a threefold to sevenfold increased risk of recurrent OASIS with subsequent deliveries [128–130]. However, these findings have not been replicated by other equally large retrospective studies [131,132]. Further prospective long-term studies are required before elective cesarean section can be recommended for prevention in asymptomatic women.

PFMT in the Prevention of OASIS

For women without FI, PFMT might be preventative. For example, in one study treating women with persistent SUI 3 months after delivery, lower rates of FI were seen compared with controls [70]. It is recommended that women with OASI receive supervised PFMT as a form of secondary prevention. However, as with SUI, a randomized trial showed that the significant improvement in FI compared to controls at 1 year (4% vs. 11%) did not persist at 6 years (12% vs. 13%) irrespective of subsequent deliveries [93].

These research findings have focused the attention of obstetricians and midwives to the potential risk of anal sphincter injury and the possible association with long-term FI. This should result in improved awareness, training, and prevention.

Other nonobstetric modifiable risk factors for FI including obesity, SUI, and associated medical conditions such as irritable bowel syndrome have been identified [133,134]. Addressing these might also help in prevention.

PREVENTION OF INCONTINENCE AND PROLAPSE FOLLOWING GYNECOLOGICAL SURGERY

Hysterectomy and Incontinence

Urinary tract fistulae are (fortunately) rare, but are not always preventable. A rate of 0.5%–3% of lower urinary tract injury has been reported at hysterectomy. Many of these are due to congenital abnormalities and distortion of structures caused by disease [135]. Preoperative intravenous urography, intraoperative cystoscopy, and the use of ureteric catheters in potentially difficult cases might help prevent trauma to the urinary tract. An increased risk of UI after hysterectomy has also been reported. In a systematic review, women over the age of 60 years who had undergone hysterectomy had a higher odds ratio compared with women less than 60 years [136]. Overall, the estimates suggest a 60% increased risk of developing incontinence after hysterectomy. How this can be prevented is unclear, but with a reduction in the number of hysterectomies for menorrhagia, by the use of progesterone-containing intrauterine devices and endometrial ablation, posthysterectomy incontinence might become less prevalent. Consideration might be given to concomitant continence surgery as secondary prevention for women with preexisting urodynamic stress incontinence, requiring hysterectomy. This has been shown to improve the chances of continence at 1 year postoperatively [137]. However, there is no evidence that this is indicated for primary prevention. For “occult SUI,” see the following text.

It has been suggested that subtotal hysterectomy might reduce the incidence of UI [138], as the cervix might act as a posterior support for the sphincter mechanism. It is also thought that division of the cardinal ligaments can result in denervation [139]. However, RCTs have failed to show any benefit of subtotal over total hysterectomy with regard to the onset of UI [140–142]. On the basis of current evidence, UI does not seem to be adversely affected in the short term following hysterectomy. However, there is an association with incontinence in the long term [136]; therefore, preventative measures need to be investigated. A systematic review of 9 trials with 1553 participants has not shown improved outcomes for sexual, urinary, or bowel function with subtotal hysterectomy compared to total abdominal hysterectomy either in the short term of long term [143].

Hysterectomy and POP

The risk of vaginal vault/apical prolapse and enterocele following hysterectomy has been reported as 3.6/1000 person-years. The risk increases from 1% (at 3 years) to 5% (at 15 years) [31]. After colposuspension, the incidence of new-onset enterocele has a reported incidence of 18%–30% [144,145]. Possible causes of postsurgical POP include reduced and weakened collagen [9,146]. failure to support the vault at hysterectomy or "anteversion" of the anterior vaginal wall following colposuspension. Similarly "retroversion" of the vaginal vault at sacrospinous ligament fixation can result in a high incidence of cystocele (see Chapter 100, "Laparoscopic Sacrocolpopexy"). Prevention will depend on the surgical procedure, the technique, and the strength of the supporting structures.

It is generally accepted that apical support is the key to preventing recurrence of vault prolapse following hysterectomy [147,148].

For example, laparoscopic and robot-assisted sacrocervicopexy with supracervical hysterectomy and sacrohysteropexy have been reported to have good success rates, but these findings need to be confirmed by randomized controlled studies [149].

Prevention of Urgency Urinary Incontinence after Surgery for Urodynamic Stress Incontinence

Midurethral Tapes

There are few data on whether midurethral slings, e.g., tension-free vaginal tape (TVT), have a better effect in the prevention of de novo urgency symptoms/DO than colposuspension. In a large RCT comparing the two procedures, the incidence of new-onset urgency and urgency incontinence was less than 2% for TVT and less than 5% for colposuspension at 5 years [150], although this might be an underestimate given the high incidence (over 90%) of preoperative OAB symptoms in both groups in this study. In a follow-up of patients 7 years after TVT, 22.5% had "urge symptoms." In a further 6.3%, this was "de novo" [151], similar to the 9.1% incidence reported by other authors [152]. In those with preoperative OAB symptoms, 57% resolved after surgery [152]. From these case series, it would appear that the incidence of urgency incontinence and OAB after TVT is similar to that reported after colposuspension. Likewise, the rate of de novo urgency and urgency incontinence after transobturator tape (TOT) seems to be comparable to that of TVT [153,154] and Burch colposuspension [155].

Colposuspension

Following colposuspension (an operation done less frequently since the introduction of midurethral tapes but nonetheless still undertaken), OAB (± DO) with urgency incontinence can arise in 15%–18.5% of cases [145,156]. Overelevation of the bladder neck (>2.6 cm on MRI) with obstruction has been implicated [157], but no reliable intraoperative method has been found to reproduce the 2.6 cm measurement of elevation; it can only be done subjectively. It is recommended that excessive elevation be avoided by whatever surgical technique.

Preoperative SUI or UUI is the most important predictor of SUI and UUI postoperatively [158]. However, new-onset incontinence is a particularly worrying complication following surgery for POP. It has been shown that 7%–22% of patients can develop incontinence following POP surgery [159]. It is generally acknowledged that the incidence of "occult" stress incontinence (i.e., that seen preoperatively following a pessary or POP reduction test) exceeds that actually seen after the procedure [160]. Incidence ranges from 23% [161] to 83% [162].

The pessary test can be used preoperatively in patients with POP to identify those with potential occult SUI postoperatively [163]. Five prospective studies have investigated several prophylactic anti-incontinence procedures at the time of POP surgery, including Pereyra needle suspension [164], Kelly plication [165], Stamey procedure [166], pubovaginal sling [167], and needle suspension vs. endopelvic fascial plication [159]. The latter was a small randomized trial that failed to confirm that a concomitant anti-incontinence procedure is preventative. None of these studies have a nonintervention arm ("no anti-incontinence procedure"), which makes difficult to determine and compare the risk of postoperative incontinence with those not having an anti-incontinence procedure.

The potential role of prophylactic midurethral sling (TVT) has been evaluated in two controlled case series, which report conflicting results. One small retrospective trial involving 19 patients [168] reported no difference between the groups, while another prospective trial [169] reported significant reduction in the incidence of postoperative incontinence in the women undergoing prophylactic TVT.

The most rigorous study into the prevention of potential/occult incontinence, the Colpopexy and Urinary Reduction Efforts (CARE) study [170], randomized 322 women undergoing sacrocolpopexy into concomitant Burch colposuspension and no intervention. They demonstrated a significant reduction in postoperative stress incontinence at 3 months, which seems to be maintained at 2 years [171]. The pessary test and preoperative urodynamics were not very helpful in predicting outcome. A prediction model with a level III evidence has also been proposed to predict the risk of de novo SUI in women undergoing POP surgery [172]. A recent systematic review has concluded that combined anti-incontinence surgery and POP surgery reduces the risk of postoperative stress incontinence, but short-term voiding difficulties and adverse events were more frequent [173]. A review suggested that women undergoing prolapse surgery may have benefited from having continence surgery performed concomitantly, especially if they had SUI (RR 7.4, 95% CI: 4.0–14) or if they were continent and had occult SUI demonstrated preoperatively (RR 3.5, 95% CI: 1.9–6.6) [174]. A recent RCT has however questioned the policy of routine sling insertion at the time of surgery for POP [175].

Since these results cannot be extrapolated to other anti-incontinence procedures/POP operations, further research is required.

In the meantime, it is advisable to warn patients of the potential risk of incontinence and the possible need for treatment in the future.

However, there is not enough evidence to counsel patients on prophylactic surgery at present. Minimally invasive midurethral slings might allow for secondary surgery as an “interval” procedure in those who do develop “occult” SUI.

Recurrence of Stress Incontinence after Vault Suspension: Prevention

A rare but potentially distressing scenario is recurrence of stress incontinence (SUI) following vault prolapse surgery in patients who have had a previously successful colposuspension. While there are fewer of these procedures being performed since the introduction of midurethral tapes, nonetheless about 30% of patients can develop symptomatic prolapse requiring surgery with the potential risk of recurrence of SUI. The exact prevalence is unknown. However, a case study highlighted this risk and suggested methods of prevention [176]. For example, measuring that vault elevation (in cms from the hymen) preoperatively that will not result in demonstrable SUI and reproducing it at sacrocolpopexy might prevent this complication. Also, performing sacrospinous fixation under spinal anesthesia allows the patient to perform a cough stress test, thus enabling alterations in the placement of the sutures to prevent incontinence [176]. These reports highlight the need for “vigilance” and to be aware of the possible risk of rendering a patient incontinent again despite previously successful incontinence surgery.

Prevention of Failed Surgery for Incontinence and Prolapse

SUI Surgery

The usually quoted success rates for USI surgery are 80%–90% [145].

However, these rates might be less depending on the definition of success/cure. Using patient-reported outcomes only and satisfaction, the success rates are often less than those quoted earlier [177]. Reasons for poor outcome include previous incontinence surgery and intrinsic sphincter deficiency (ISD). For example, a 54% failure rate has been reported in patients with ISD [178] although this is not a consistent finding [179]. Other predictors of treatment failure 2 years after surgery for USI including urgency incontinence, more advanced prolapse, and postmenopausal status (not on HRT) have been reported [180]. These are difficult to modify but might need to be considered when counseling women on the operative prognosis.

Studies are required to compare the various surgical procedures for ISD, such as slings, colposuspension, injectables, and midurethral tapes so that failure can be prevented. A recent randomized trial comparing the efficacy of TVT vs. TOT in women with ISD found that a significantly higher proportion or women in the TOT group had urodynamic stress incontinence at 6 months follow-up (45% vs. 21%) and that more women in the TOT group required repeat sling surgery [181]. It therefore seems that TVT might be a more appropriate operation for this group of patients.

The surgical “gold standard” for USI due to bladder-neck “hypermobility” has been the Burch colposuspension [182]. although the midurethral tapes (e.g., TVT) have comparable short- and medium-term outcomes [150,151]. The longest follow-up data for TVT suggest that at 17 years about 90% of women are still cured or significantly improved [183]. Prevention of failed surgery might be achieved by avoiding procedures with a poor success rate (e.g., anterior repair) or those that have not been fully evaluated or failed to show benefit over colposuspension or TVT. Attention to the aforementioned should lead to a reduced failure rates with surgery. The old adages are still apt: "the first operation must be the best one" and we should "choose the right operation for the right patient and the right patient for the right operation." The latter will depend on factors such as obesity, age, previous surgery, concomitant prolapse, and DO. In addition patient expectations and goals should be assessed preoperatively and whether they achieved after surgery [184].

Pelvic Organ Prolapse Surgery

Cystocele/anterior repair has long been known to have a high anatomical failure rate [185] with incidences as high as 40% being quoted [186]. The reasons for failure are unclear and might be related to surgical technique, patient selection, poor tissue collagen, etc. It is also possible that the anatomical defects associated with cystocele have not been corrected. For example, it is known that in many cases the anatomical defect is a detachment of the paravaginal fascia from the arcus tendineus fascia pelvis/"white line." It is unlikely that an anterior repair, which is a midline fascial plication, will correct this defect; paravaginal repair might be more appropriate. However, it's been shown with MRI scanning that 50% of paravaginal defects can be corrected with traditional anterior repair [187]. While success rates of 76%–97% have been quoted [188], a RCT is required to determine if paravaginal repair produces a better outcome than anterior repair in cases of paravaginal defect.

Based on 56 RCTs, a recent Cochrane review showed that for surgical management of upper vaginal prolapse (uterine or vault), abdominal sacral colpopexy had superior outcomes (reduced recurrent vault prolapse) compared to a variety of vaginal procedures including sacrospinous colpopexy, uterosacral colpopexy, and transvaginal mesh, but was associated with a longer operating time, longer time to return to activities of daily living, and increased cost of the abdominal approach [174]. The Cochrane review also evaluated 21 trials and compared a variety of surgical procedures for anterior compartment prolapse (cystocele) and showed that standard anterior repair was associated with more anterior compartment prolapse on examination and the use of mesh or graft inlays at the time of repair reduced the risk of recurrent anterior wall prolapse on examination [174]. Anterior vaginal polypropylene mesh also reduced awareness of prolapse; however, these benefits must be weighted against increased operating time, blood loss, rate of apical or posterior compartment prolapse, de novo SUI, and reoperation rate for mesh exposures associated with the use of polypropylene mesh [174]. This Cochrane review also showed that posterior vaginal wall repair may be better than transanal repair in the management of rectocele in terms of recurrence of prolapse and there was paucity of evidence to support use of grafts at the time of posterior vaginal repair [174].

Several surgical techniques have been tried to prevent recurrent POP, mainly aimed at reinforcing apical support (see section "Hysterectomy and POP").

The use of vaginal grafts/meshes to prevent recurrence of prolapse was introduced despite a lack of supporting evidence on long-term efficacy and safety. There are numerous studies investigating a wide variety of vaginal meshes for either anterior, posterior, or upper compartment prolapse (or combinations of them). However, in 2008 the U.S. Food and Drug Administration issued a warning with regard to the safety and lack of evidence of efficacy of vaginal meshes when compared to native tissue repairs, which they updated in 2011, stating that serious complications associated with surgical mesh for transvaginal repair of POP are not rare. Furthermore, it is not clear that transvaginal POP repair with mesh is more effective than traditional nonmesh repair in all patients with POP, and it may expose patients to *greater risk* [189]. Since then several meshes have been removed from the market in view of complications and litigation. The use of transvaginal mesh for POP remains highly controversial and further large, well-conducted RCTs are required. The results of one such study in the United Kingdom (*PRO*lapse *S*urgery: *P*ragmatic *E*valuation and randomised *C*ontrolled *T*rials [PROSPECT]) are awaited.

Prevention of Detrusor Overactivity

As the etiology and natural history of DO are unclear, prevention is difficult. There are few studies assessing long-term outcomes. Those that exist suggest that OAB is a chronic condition that persists urodynamically and symptomatically [190]. For prevention of postoperative urge incontinence, accurate diagnosis by urodynamic studies might help avoid unnecessary surgery in patients who have DO and not USI. It is possible that DO might have its origins in childhood (see section "Familial and Genetic Factors"). For example, patients with persistent primary nocturnal enuresis have a high incidence of DO

[191]. In an attempt to prevent symptoms in their children, some mothers with OAB often “toilet” the children more frequently [192,193]. This might be counterproductive as frequent voiding might develop into urgency and urge incontinence. Although none of the studies cited here are large or the findings conclusive, nonetheless they highlight the need for further investigation in this area. Should symptoms in childhood be relevant to the etiology of DO, then education of parents regarding toileting and bladder drill might be preventative. Psychological factors have been implicated in the etiology of DO [194,195]. Identification together with appropriate psychotherapy has shown encouraging results [195]. This might also prove valuable in prevention. Anecdotal evidence suggests that a high fluid intake is associated with symptoms of frequency and urgency. Restricting bladder stimulants (e.g., caffeine and alcohol) should be considered. Finally, the “integral theory” suggests that bladder-neck opening (due to a weak anterior vaginal wall) might lead to the development of DO [196]. PFMT might therefore have a role in prevention. However, long-term studies are needed to test this hypothesis. Further research is needed into the etiology of DO, which might be multifactorial. In the meantime, prevention can only be speculative.

CONCLUSIONS

The natural history of incontinence and POP requires more study, but there is evidence that spontaneous remission occurs. Effective prevention will only be achieved by long-term prospective studies of appropriate interventions in “at-risk” groups.

Some of the preventions are as follows:

- Treatment of coexisting factors, such as obesity, chronic cough, or constipation, might help in the primary and secondary prevention.
- Studies of interventions in children with symptoms and asymptomatic individuals with a strong family history of incontinence and/or POP.
- Further research is required to assess the preventative effects of hormone replacement in menopausal women.
- Long-term follow-up of patients with incontinence as a result of pregnancy and vaginal delivery is required before elective cesarean section can be recommended for prevention. PFMT seems to have a beneficial effect in “at-risk” groups at least in the short term. However, methods to improve compliance are required if the effect is to be maintained.
- Attention to the potential risk of incontinence following hysterectomy or POP surgery is suggested. For a patient to be rendered incontinent, following unrelated surgery is distressing; measures to identify the risk and prevent this outcome should be considered.
- Further research is required to identify the reasons for poor treatment outcomes.

With attention to the aforementioned and the natural history, appropriate preventative measures should be found to protect women from incontinence and POP.

10 Medical Error and Patient Safety in Surgery

Roxane Gardner

INTRODUCTION

By nature of the human condition, surgery-related errors and adverse events are inevitable. Consequences from these events directly and indirectly affect patients and their families and surgeons and their colleagues throughout the world wherever such events happen to occur. The exact number of surgical procedures performed worldwide is not known. Information about inpatient procedures is more readily available, but the quality and scope varies by location. Weiser et al. [1] analyzed a variety of data obtained from the World Health Organization (WHO) member states and found only 29% of the member states collected information on surgical volume, and none had reliable data about inpatient death rates or adverse events. Given these limitations, they estimated that a minimum of 234.2 million major surgical procedures are performed annually, most occurring in countries with high health expenditures per capita. Their definition of major surgery included any intervention taking place in a hospital operating room (OR) involving incision, excision, manipulation or suturing of tissue requiring profound sedation, and regional or general anesthesia for pain control. Based on a 0.5% perioperative mortality rate and a 3% perioperative adverse event rate, they estimated that 1 million surgery-related deaths and 7 million major complications occur as a result of such procedures. Furthermore, data available from developed countries indicated that about half of surgical adverse events were deemed to have been preventable.

Information is uneven and less readily available regarding outpatient surgery procedures performed worldwide. Global analysis as of February 2014 reported that the site of surgery has shifted over the past few decades from the inpatient to outpatient settings [2]. Outpatient surgical procedures in the United States has definitely increased, comprising about one-third of all surgical procedures in 2000 to more than half by the end of 2010 [3]. This trend is expected to continue albeit on a slower trajectory due to continued growth in the aging population and the proportion with high medical case complexity necessitating an inpatient surgery venue. Healthy patients deemed at low risk for adverse events are typically selected for outpatient procedures. However, more complex patients may be selected for outpatient surgery as less invasive techniques become available and economic factors, including changes in cost and reimbursement for health-care services, drive provision of services away from hospital inpatient settings.

Similarly, the precise number of female urology and urogynecology inpatient operative procedures performed worldwide is not known. Where data are available, the rates of specific female urology and urogynecology surgical procedures appear to be on the rise. For example, Oliphant et al. [4] analyzed the National Hospital Discharge Survey (NHDS) database and determined that age-adjusted rates for inpatient stress urinary incontinence (SUI) procedures performed in the United States between 1979 and 2004 more than doubled from 0.64 to 1.60 per 1000 woman. They projected that both the overall and age-adjusted rates would continue to increase over time since about 20% of the U.S. population is expected to be 65 years or older by 2030, most of whom will be women [5]. The exact number of female urology and urogynecology outpatient surgical procedures that are performed worldwide is also not known but appears to be growing. In the United States, Boyles and colleagues [6] found that female urinary incontinence procedures performed in the outpatient setting doubled between 1994 and 1996. Furthermore, Jonsson, Funk, Levin, and Wu [7] reported a 27% increase in the overall rate of SUI surgical procedures between 2000 and 2009, the highest rate being for sling procedures. They also reported that 67% of all SUI procedures were performed in the outpatient setting during this specific 10-year period.

Patient safety is a serious international public health-care issue [8]. Interest has been growing over the past decade to better define the role of surgical care among other global health priorities and its role in addressing the global burden of disease [9]. Given the volume of surgery estimated to take place worldwide and the shift in the site of surgery from inpatient to outpatient settings, it would behoove surgeons of all specialties to understand how multiple factors can contribute to error such as factors related to cognition, fund of knowledge, clinical judgment, diagnostic problem-solving, and decision-making; technical skills, communication, and teamwork; supervision and documentation; administrative; and clinical systems and environment. It is imperative that surgeons of all specialties develop and master techniques for mitigating or preventing errors, resulting in adverse surgical events and patient harm across the continuum of surgical care. Fortunately, multiple efforts are underway worldwide to make healthcare safer for patients and clinicians [8,10,11]. This chapter will provide an overview of medical errors and adverse events and address multiple efforts aimed at preventing their occurrence or mitigating their effects in the surgical setting. Specific clinical approaches for improving quality and safety of patient care such as prophylaxis for infection and deep venous thrombosis and the prevention of retained objects and safe introduction of new technology will be covered elsewhere.

PATIENT SAFETY AND MEDICAL ERRORS

Patient safety, the prevention of harm to patients, is regarded by the Institute of Medicine (IOM) as inseparable from quality of care [12]. Safety is the first domain of quality. All patients expect and deserve safe care. Their care should be free from hazards that increase the likelihood of adverse events or harm. The call to action in 2000 by the IOM to improve patient safety and decrease medical error was driven in large part by findings from two signature studies in the United States. These researchers reviewed medical records of hospitalized patients to estimate the rate of adverse events and negligence occurring in the states of New York, Colorado, and Utah. In New York, adverse events were found to have occurred in 3.7% of hospitalizations, and 27.6% of the adverse events were due to negligence [13]. In both Colorado and Utah, adverse events were found to have occurred in 2.9% of hospitalizations, and more than 25% of these cases were due to negligence [14]. The landmark study involving Colorado and Utah showed that operative adverse events accounted for 44.9% of all adverse events identified and 16.9% of these were due to negligence. Poor surgical technique accounted for 29.9% of surgical adverse events, 23.6% of which were due to negligence. Bleeding, infections, and deep venous thrombosis were the next most common surgical adverse events identified. Overall, surgical technique–related complications, infection, and bleeding accounted for about half of all surgical adverse events. The rates of adverse events identified in these studies extrapolated to the population of all patients hospitalized in the United States during 1997 placed medical errors among the eighth leading cause of death [15], exceeding causes due to car accidents, breast cancer, or AIDS. A more recent analysis in 2013 by James [16] examined information from four separate studies published during 2008–2011 about preventable adverse events in hospitalized patients. Each of these studies employed the Global Trigger Tool [17] as the core method used by trained health-care professionals to extract data from medical records and determine if an adverse event may have harmed a patient. He concluded that a lower limit of 210,000 deaths per year of hospitalized patients was associated with preventable harm, and the true number may be upwards of 400,000 deaths per year. He noted that nonlethal but serious harm was 10- to 20-fold more common than lethal preventable adverse events. Based on James' analysis and preliminary data on deaths in the United States for 2011 [18], deaths due to preventable adverse events would more likely be the third leading cause of death in 2011 compared to the eighth leading cause of death in the United States in 1997.

Around the world, the year 2000 was pivotal in the call to action to improve safety of patient care and decrease medical errors. The National Health Service (NHS) of the United Kingdom in 2000 reported on the occurrence of health-care-related adverse events and their impact on patients and their families, clinicians, and NHS organizations [19]. In their landmark report, *An Organisation with a Memory,* they stated that preventable errors are the result of human error whether intentional or not. They also highlighted the relationship between human factors and medical errors. The launch of patient safety initiatives in Australia occurred around this same time. Lessons learned from the Australian incident monitoring study of the 1980s [20,21] did much to inform their efforts to improve patient safety in their country. Similar awareness and patient safety initiatives began in New Zealand around 2001 [22]. Canada released a multifaceted action plan to improve patient safety, *Building a Safer System*, in 2002 [23]. The WHO passed a resolution in early 2002 urging countries to pay the greatest possible attention to patient safety and establish evidence-based systems to improve safety and quality healthcare worldwide [11]. Successful efforts in such endeavors led to the formation of the World Health Alliance for Patient Safety in 2004, and the Global Patient Safety Challenge to *Safe Surgery Saves Lives*—improving the safety of surgery around the globe [24].

Fundamental to the global call to action to improve patient safety is the understanding that "to err is human" [25]. James Reason asserted in 1990 that errors are inevitable and an acceptable price to pay in coping with difficult, complex tasks [25]. In his landmark book, *Human Error*, he described a framework for human error, highlighting the relationship between various aspects of human cognition and error. His framework differentiated three error types—"skills-based slips and lapses, rule-based mistakes and knowledge-based mistakes" [26]. He stressed that understanding the differences between these error types helps to identify suitable means by which to intervene and address them. To that end, James Reason promoted two main approaches by which to deal with the problem of human error: the person approach and the systems approach [27]. The person approach embodies the long-standing tradition of targeting and blaming individuals for errors. The systems approach accepts the fallibility of human nature and expects errors. The systems approach scrutinizes how and why defenses fail and designs ways to trap or minimize the effect of errors via measures that address the person, the team, the workplace, and the institution as a whole. This concept embodies a "just culture," a concept that resonated with the IOM as evidenced by their strong advocacy for such approach to human error, not assigning blame, and building safer health-care systems that reliably trap error and mitigate their effects [28]. The health-care industry is highly complex, and some 24-hour-a-day services are more vulnerable to error than others such as intensive care settings, the operating theater, emergency departments, and labor and delivery units. High reliability organizations (HROs) are known to exemplify the systems approach to human error [29].

HIGH RELIABILITY ORGANIZATIONS

An HRO is one that operates in hazardous conditions 24 hours a day under the pressure of time but with fewer than expected accidents, "less than their fair share of adverse events" [30]. Examples of such organizations include naval aircraft carriers, nuclear power plants, offshore oil platforms, and air traffic control systems. Around the world, more and more hospital emergency units, operating theaters, and perinatal units are striving to transform themselves into HROs. All HROs strive to manage the unexpected with determined mindfulness. Weick and Sutcliffe assert that "good management of the unexpected is mindful management of the unexpected" [31]. HROs are characterized by a shared commitment to safety throughout the organization and distinguish themselves by their "collective preoccupation with the possibility of failure" [32]. Preoccupation with failure involves anticipating and recognizing where failure can occur and taking measures to prevent it. Standardizing procedures where possible and taking stock of where and when adverse events and near misses may occur facilitate error prevention or mitigating their effect. Establishing effective systems for reporting errors and adverse events further optimizes the ability to track them and opportunities to learn from them. HROs are not error-free but are resilient when error occurs. One way HROs manifest a preoccupation with failure is by training their personnel and teams intensively through drills and simulations.

CULTURE OF SAFETY

HROs manifest a positive culture of safety. An organization's culture of safety is the product of individual and group values, skills, and behaviors that shape an organization's commitment to and proficiency of their own safety programs [33]. A simple way to think about culture is "the way we do things around here and why we do them" [34]. Edgar Schein [35] advocated analyzing organizational culture at three levels to better understand shared basic assumptions and the processes by which they came to be. He asserted that the knowledge gained could then be used to facilitate organizational culture change as needed. The first level is comprised of observable behaviors that are evident in the workplace; the second level consists of the beliefs and values espoused by members within the organization; and the third level, perhaps the most important, consists of the basic underlying assumptions that may be taken for granted, are largely subconscious, and are not verbalized. According to Schein, these underlying assumptions may best inform why things unfold within an organization the way they do. For example, moving from a culture of shame and blame to one that is nonpunitive yet preserves accountability can provoke high anxiety for members in the organization and present challenging obstacles and consumption of valuable resources, especially the element of time. The IOM acknowledged that one of healthcare’s biggest challenges in providing reliably safe, high-quality care was changing from a culture of shame and blame to one that is fair and just [12].

Establishing a safe and just culture is not an easy task and cannot be mandated [34]. Moving toward a culture of safety takes time, and incremental steps are needed to facilitate and solidify the change if it is to be longlasting. Transparency, professional responsibility, mutual accountability, and nonnegotiable mutual respect are among the key elements of a systems approach to error management [36–38]. Individual health-care providers are responsible for ethical practice, clinical competency, and mindfulness in the provision of safe patient care.

HUMAN FACTORS AND THE DEMANDS OF CLINICAL PRACTICE THAT WEAKEN DEFENSES

Humans are integral to the provision health-care services and therefore to the safety and quality of care they provide. Not all human errors result in adverse events, events that unexpectedly result in death, injury, extended hospital stay, or disability. However, most adverse events are preventable. Understanding how and why errors and adverse events occur provides a road map by which to obviate them. The study of human fallibility and the science behind why errors happen and how to mitigate and prevent their occurrence are encompassed by the field of human factors. Much has been written about human factors and their contribution to errors in the military and aviation and nuclear industry [39–41]. Human factors involve the interactions among humans and elements in their systems and the application of theory, principles, data, and methods designed to prevent error and optimize human and system performance. Calland et al. [42] articulated in 2002 the virtues of taking a systems approach to surgical safety. This sentiment was echoed in 2004 by Vincent et al. [43] They argued for a wider assessment of factors that may be relevant to surgical outcomes and the development of an “operation profile,” a characterization of all the salient features of a surgery including equipment design and use, communication and team coordination, and factors affecting individual performance and the working environment (see Table 10.1).

According to Catchpole [44], tremendous progress has been made over the past decade in the degree to which health-care providers have become aware of the role and value human factors can play in achieving better and safer human-centered health-care systems.

The limitations of being human in combination with certain features of clinical practice within which health-care providers work often create challenges for delivering safe, high-quality care. Veltman [45] highlighted several clinical practice–related issues and inherent demands that weaken defenses to error and contribute to perinatal harm. These practice-related issues and demands, expanded from those of Veltman, are applicable to the field of surgery regardless of the specialty and locus of surgery-related activities, whether inpatient, outpatient, or office based (see Tables 10.2 and 10.3).

The following human factors’ focus areas were identified by Russ et al. [46] as being applicable to healthcare: aging, cognition, cognitive engineering and decision-making, communication, human performance modeling, industrial and macroergonomics, perception and performance, product design, safety, training, and usability–user experience when interacting with a product or system. They stress that the science of human factors does not promise instant solutions for improving healthcare. However, the partnership of human factors professionals with health-care professionals can generate relevant and long-term solutions designed to systematically address clinical practice–related issues and strengthen clinicians’ defenses to error, thereby facilitating patient safety and quality of healthcare. Shouhed et al. [47] further underscored the importance of building collaborations between human factors experts and surgeons to better understand the complexity of factors leading to surgical errors and use valid, real-world data to develop evidence-based interventions that detect and prevent errors before patient harm occurs.

Table 10.1 Operation Profile

Item	Features
Patient factors	Principal complaint Comorbidities Other relevant clinical information
Surgical team	Personnel

	Experience of previous work together Familiarity with procedure Fatigue, sleep loss, stress, etc.
Process and procedures	Adequacy of notes and management plan Consent and preparation Anesthetic procedures
Operative events	Blood loss Major and minor complications Error compensation and recovery
Flow of information following patient	Adequacy of notes and consent Specific intraoperative communication Handover
Technical skills	Ratings of good general surgical practice Ratings of operation-specific steps Identification of specific technical errors
Team performance and leadership	Leadership Team coordination Willingness to seek advice and help Responsiveness and flexibility
Decision-making and situation awareness	Patient limitations Operation limitations Surgeon’s limitations Team limitations
Operative environment	Availability and adequacy of equipment Availability of notes, records, etc. Noise and lighting Distractions
Interruptions	Phone calls, messages, events external to operating room

SOURCES OF ERROR IN SURGERY

In their classic study published in 2006, Rogers and colleagues [48] retrospectively analyzed malpractice claims from four liability insurers that contained allegations of surgical error and had closed between 1986 and 2004. Of 444 surgical claims reviewed, 258 (58%) were confirmed as being due to surgical error. The majority (76%) were elective procedures involving the gastrointestinal tract (29%), spinal and nonspinal orthopedic procedures (24%), hysterectomies (7%), and the genitourinary tract (5%). Most injuries (75%) had occurred during the intraoperative period. The severity of the injury was deemed significant (temporary major, permanent minor, and permanent significant injury) in 55% and major (permanent major and permanent grave injury) in 10% and resulted in death in 23%. Most (54%) surgical injury–related cases were due to errors in operative technique, in which most (83%) involved more than one clinician. Surgical injury–related cases were analyzed for factors contributing to the occurrence of the error. These contributing factors included cognitive errors involving judgment (66%) or failure of memory or vigilance (63%), lack of technical competence or knowledge (41%), or communication breakdowns (24%) such as inadequate handoffs, unclear lines of responsibility, or conflict among personnel. Patient factors such as excess weight, difficult or unusual anatomy, and behavioral issues also contributed to the occurrence of surgical error. Other system factors contributing to surgical error included lack of supervision (18%), failed technology (15%), and excessive workload/inadequate staffing, fatigue, interruptions/distractions, and issues related to lighting or setup. Three contributing factors were the median number found per case. Overall, 82% of cases involved system factors, human factors that are not cognitive related. Although data were limited to closed malpractice claims and overrepresented academic medical centers, their analysis characterized how human factors contribute to the occurrence of surgical error and can help to identify strategies by which to reduce patient harm.

Table 10.2 Practice-Related Issues Contributing to Patient Harm

Issue	**Example**

Regional variation in surgical practice	Deficient or inadequate guidelines, policies, or procedures Lack of adherence to guidelines, policies, or procedures
Variation in operative expertise	Surgical experience and technical skill
Uncertainty in clinical care	Presentation Diagnosis Risk assessment Management Adherence to treatment Response to treatment
Resource limitations	Staff Space Equipment Time
Wishful thinking	"Fallacy of the low-risk patient"—continuing to perceive and manage a patient as low risk when their clinical circumstances have become high risk

Source: Modified from Veltman L, *Obstet Gynecol*, 10(5), 1146, 2007.

Table 10.3 Inherent Demands That Weaken Defenses to Error

Demands of clinical practice
Presence demanded in more than one place at the same time
Critical decision-making under stress
High clinical volume, largely normal patients
Increasing growth in elderly population with comorbidities
Off-site monitoring of high-risk clinical situations
Frequent handoffs and inadequate sign-out
Protocols inadequate for referrals, consultations, or patient transfers
Frequent interruptions and distractions
Fatigue, stress, etc.
Hierarchical systems
Poor teamwork and communication
Yielding to patient pressures regarding clinical practice
Overconfidence (hubris)

Source: Modified from Veltman L, *Obstet Gynecol*, 10(5), 1146, 2007.

The need for patient safety initiatives to be implemented in the outpatient setting was stressed by Bishop et al. [49]. These investigators reviewed paid malpractice claims data contained in the U.S. National Practitioners Data Bank from 2005 through 2009, involving adverse events in the inpatient and outpatient setting. They found that the number of claims overall significantly decreased ($p < 0.001$) in both settings, but the rate of decline was greater ($p < 0.001$) for the inpatient compared to the outpatient setting. Of claims paid in 2009, they found that surgical adverse events were most common (34%), followed by diagnosis-related adverse events (21.1%) and treatment/medication related (20.3%). Whereas in the outpatient setting, diagnosis-related adverse events were most common (45.9%), followed by treatment/medication related (29.5%) and surgical related (14.4%). However, major injury was the most common outcome in the inpatient (37.8%) and outpatient (36.1%) setting, and death was the second most common outcome in the inpatient (36.1%) and the outpatient (30.6%) setting. Bishop et al. raised concerns about the growing shift in surgical care and procedures from inpatient to outpatient settings and the potential for increased risk of surgical adverse events in outpatient surgical centers or physician offices where safety measures were less stringent compared to hospitals.

SURGICAL ERROR IN FEMALE UROLOGY AND UROGYNECOLOGY

Data regarding sources of error, adverse events, and their preventability in female urology and urogynecology procedures are limited. In 2002, Brown and colleagues [50] used 1997 NHDS and 1997

National Census databases to estimate the prevalence, morbidity, and mortality of pelvic organ prolapse surgery. They found that pelvic organ prolapse surgery was common, 22.7 per 10,000 women in the United States and 21% of these also had an incontinence procedure. Mortality occurred in 3 per 10,000 surgeries. Notably, 15.5% of all pelvic organ prolapse surgeries were complicated by infection (5.4%), bleeding (5.4%), and surgical injury (4.2%).

Waetjen and colleagues in 2003 [51] reviewed the 1998 NHDS and 1998 National Census databases to estimate prevalence, morbidity, and mortality rates for SUI inpatient surgeries in the United States. Adjusting for population growth, they found a 45% increase in the frequency of such surgeries between 1988 and 1998. Retropubic suspension was the most common procedure performed (46%), followed by anterior repair (27%) and other SUI procedures (14%). Mortality from stress incontinence surgery was low at 1 per 10,000 surgeries. However, 18.3% had 1 or more complications of which nearly half were due to infection (44%), surgical injury (24%), bleeding (16%). This analysis was limited to incontinence surgery requiring hospital admission, not accounting for those performed in the outpatient or office-based setting and their associated injuries or adverse events.

Gilmour and Baskett [52] in 2005 found a low rate of urinary tract injury (3 per 1000 surgeries) at a benign gynecological surgery in Canada. However, such injury was associated with a high risk (91-fold) of litigation. Gilmour et al. [53] noted in 2006 that the most common major surgery in gynecology worldwide is the hysterectomy. They found a low rate of urinary tract injury (bladder or ureter), ranging from less than 1 per 1000 (subtotal hysterectomy with or without bilateral salpingo-oophorectomy) to 13 per 1000 surgeries (laparoscopic hysterectomy with or without bilateral salpingo-oophorectomy). A Cochrane review of surgical approach to hysterectomy by Nieboer et al. [54] also noted a higher rate of urinary tract injuries with laparoscopic compared to an abdominal approach. In France, David-Montefiore et al. [55] conducted a prospective, observational, multicenter study of women undergoing hysterectomy for benign disease between June and December 2004. Of 634 procedures performed, they found perioperative complications occurred in 5.8% of the laparoscopic approaches, 8.2% of vaginal approaches, and 18% of abdominal approaches. However, they found no differences in rates of intraoperative complications regardless of the surgical approach. Intraoperative complications included injury to the intestinal tract (~0.8%), urinary tract (~2%), and bleeding (~1%), whereas postoperative complications where more likely due to infection (~1%–2%) and bleeding (~2%).

Most recently, Edozien [56] examined malpractice claims related to gynecology filed between 2001 and 2011 in the UK NHS Litigation Authority. Gynecology accounted for 4% of open claims as of March 31, 2011, compared to obstetrics (20%) and surgery (8%). Most of the 3757 gynecology-related claims revolved around events that occurred in the OR. Causes of claims in gynecology entailed wrong diagnosis (20%), intraoperative problems such as damage to adjacent organs (17%), inappropriate treatment (14%), failure/delay in treatment (9%), failure/delay in diagnosis such as missed ectopic pregnancy or cancers of the reproductive tract (8%), failure to obtain valid consent (5%), failure to recognize complication (4%), operator error (3%), failed sterilization (2%), and failure to perform operation (2%). Of note, injuries involved the bladder in 30%; additional/unnecessary operations, such as reoperation for retained foreign object or unplanned removal of one or both ovaries, occurred in 17%; unnecessary pain occurred in 11%; and bowel damage or dysfunction occurred in 5%.

The extent to which these complications and incidents were due to human error and were deemed preventable was not specifically assessed in any of these studies. However, operative skills and technique accounted for most surgical adverse events that led to injury, bleeding, and infection. Edozien’s analysis highlights the critical role of human error in surgical adverse events and further substantiates the intraoperative period as being a priority area for patient safety interventions.

METHODS FOR MITIGATING ERROR AND MANAGING THEIR EFFECTS

Over the past two decades, multiple methods have been developed within health-care communities around the world to promote safer patient care and reduce errors or mitigate their effects. Some approaches target clinical systems and environments, while others target individuals and teams. The following section will address a variety of ways to tighten up our defenses against clinical practice–related issues and demands and facilitate safer surgical care.

Importance of Teamwork and Communication

Successfully managing routine clinical and crisis situations requires expert knowledge, technical skills, sound decision-making, and optimal teamwork behaviors [57]. Teamwork is an essential component of HROs [58]. The culture of healthcare, including medical education and residency training programs, has traditionally emphasized individual attainment of a high level of medical knowledge and procedural skills and abilities, with little emphasis on effective teamwork behaviors and systems approach to problem-solving. Formal instruction and practice of optimal teamwork behaviors for multidisciplinary teams confronting routine and crisis situations was nil to absent in most health profession training programs until about 1990s. The aviation industry was among the first to confront the reality of human error's contribution to accidents and the need for various skilled professionals to learn to work together better and communicate more effectively [59]. Salas et al. [60], the aviation team training professionals, advised that the way to turn a team of experts into an expert team is by (1) fostering shared mental models of the task and team member roles, (2) training team members on teamwork skills (situation awareness, communication, team leadership, adaptability, and compensatory behavior), (3) providing team members with guided practice on skills needed in naturalistic conditions, (4) developing simulations that allow teams to experience different course of actions, (5) linking cue patterns to response strategies with respect to task and other team members, (6) training team members on each other's roles and building realistic expectations about task requirements, and (7) training team leaders to maintain shared situational awareness by providing periodic updates to team members. Team training and cockpit resource management were central components of the aviation industry's efforts to groom expert aviators into expert aviation teams in the early 1980s. Cockpit resource management, now known as "crew" resource management (CRM), focuses on acquisition of timely information and optimizing skills in leadership, teamwork behavior, problem-solving, and situation awareness [61]. Aviation CRM has evolved to include error management in its CRM curriculum, EMCRM, techniques for enhancing error recognition, management, and recovery. In 1989, Howard et al. [62] were instrumental in adapting aviation CRM to anesthesia, known as anesthesia crisis resource management (ACRM), to evoke change and improve teamwork and communication among anesthesiologists. This body of work paved the way for dissemination of ACRM to anesthesia leadership across the United States and around the world [63–66]. Helmreich and associates furthered this transformation by integrating principles of organizational behavior and culture [67,68]. Helmreich [67] played a crucial role in promoting teamwork and communication in the field of surgery, and Shortell et al. [69] were similarly key among health-care professionals working in intensive care unit (ICU) settings.

Around this same time, the U.S. Department of Defense (DoD) adapted their Army aviation CRM and introduced such training to healthcare upon realizing their aviation CRM program had produced a 20% improvement in mission performance and a 40% reduction in safety-related task errors [68,70]. This intervention was further bolstered by findings of a review conducted by Risser et al. [71] of closed malpractice claims from a total of eight military and civilian hospital emergency departments. They found that 43% of these claims involved issues related to poor teamwork and communication. As a result, the DoD sponsored the development of the MedTeams project and an Emergency Team Coordination Course, a teamwork curriculum specifically designed for emergency medicine clinicians [72].

Similar findings of inadequate teamwork and communication were appreciated in about 60% of the DoD's obstetrical closed claims—unpublished data. Likewise, an internal review of obstetrical closed claims involving Harvard-affiliated hospitals revealed that 43% had elements of poor teamwork and communication [73]. These two findings led to the expansion of the MedTeams project to include systematic teamwork and communication training for labor and delivery clinicians in civilian and military hospitals [74].

Surgical teamwork failures have been identified via a number of methods, such as voluntary reports of adverse events, malpractice claims, and during real-time observations. The Joint Commission [75] reported that communication failures were the leading root cause in 66% of sentinel events reported to them between 1995 and 2004, the leading root cause for medication errors, delays in treatment, and wrong-site surgery, and the second leading root cause for operative and postoperative events. As previously mentioned, Rogers and colleagues [48] were able to identify communication breakdowns in 24% of surgical malpractice claims they reviewed. Lingard et al. [76] in 2002 explored the nature of communication in the OR. Of 35 surgeries and 128 hours of OR interactions, patterns of conversations were observed as subtle, complex, and socially motivated. Conversations revolved around the following themes of time, safety, sterility, resources, roles, and situation. Tension surfaced regularly and one to four higher tension events arose per procedure. These events had an observable effect on members of the team, including surgical trainees who responded either by withdrawing from the conversation or by mimicking their senior surgeon. Both of these responses by trainees had negative implications for effective teamwork. Lingard et al. [77] subsequently used trained observers to study communication failures in the OR during 2003. Of 48 surgical procedures and 90 hours of observations, they identified communication failures in about 30% of team exchanges. Such failures included poor timing, incomplete or inaccurate information exchanged, issues not resolved, or key individuals excluded. About one-third of these failures were seen to visibly affect system processes and jeopardize patient safety, such as tension amidst the team, inefficiency and delays, work-arounds and wasted resources, patient inconvenience, and procedural errors. Such research by Lingard and colleagues highlights critical aspects of team communication and opportunities for interprofessional training to improve it. They deemed a curriculum to address interprofessional communication across systems and processes to be worthwhile. Tension among and between surgical teams and the occurrence of higher tension events are inevitable in the OR. How these moments are managed by members of surgical team, across the hierarchies within and between the disciplines, can directly and indirectly affect the safety of patient care and surgical outcomes.

Greenberg et al. [78] conducted an in-depth analysis of 60 closed malpractice claims with communication breakdowns resulting in patient harm, a subset of the 444 closed malpractice claims previously described by Rogers et al. [48] Communication breakdowns were about evenly divided between the preoperative (38%), intraoperative (30%), and postoperative (32%) periods. Verbal communication breakdowns occurred between 1 transmitter and 1 receiver, more commonly involving the attending surgeon. Factors associated with these breakdowns included hierarchy and power differentials and ambiguity about roles and responsibilities. Handoffs and transfer of care were problematic. Failures in resident-to-attending communication concerned notification of critical information, while attending-to-attending communication failures were related to inadequate handoffs. About 14% of cases involved intraoperative surgical sponge or instrument miscounts. These investigators proposed a series of triggers for notifying the responsible attending about clinical changes or staff concerns about a patient during the preoperative and postoperative periods. They estimated 26%–44% of communication breakdowns would have been prevented if these triggers had been used. They postulated that the use of standardized handoffs and protocols for transferring patients would have prevented 11%–35% of problematic occurrences. The combination of triggers and standardized transfers or handoffs could potentially prevent half or more of communication breakdowns. Implementation of read-back protocols, closed-loop communication techniques could further augment communication of critical patient information. They advocated for instituting structured communication techniques such as standardized team briefings, time-outs or surgical pauses to improve surgical safety, and exploring technological solutions to mitigate or prevent instrument or sponge miscounts.

SURGICAL TEAM TRAINING INTERVENTIONS

Having documented that deficiencies in teamwork contribute to the occurrence of adverse events in surgical patients, two classic studies illustrate the impact of interventions aimed at improving communication and teamwork within surgical teams. Haynes et al. [79] evaluated implementation of the WHO surgical safety checklist, a structured communication tool designed to improve communication and consistency of surgical care before administering anesthesia, immediately prior to skin incision and before the patient leaves the OR. The checklist was used in eight economically and clinically diverse hospitals located across the globe. Significant reductions were seen in death rates (1.5%–0.8%, $p = 0.003$) and intraoperative complications (11%–7%, $p < 0.001$). All sites had reductions in major postoperative complications. Although the reductions were greater in some sites than in others, the checklist program was deemed useful for improving surgical safety in a wide variety of clinical and economic settings worldwide.

McCulloch et al. [80] conducted a single institution (teaching hospital) before and after study of team skills training. They observed a series of laparoscopic cholecystectomy and carotid endarterectomy procedures before and after implementing a 9 hour aviation CRM-based teamwork training curriculum. On-site teamwork coaching was provided about twice a week for 3 months. They also evaluated Safety Attitude Questionnaires (SAQs) pre- and post-team training intervention. Formal team training led to significantly improved SAQ teamwork climate scores (*p* = 0.007), improved teamwork performance (*p* = 0.021) and reductions in technical errors (1.73–0.98 per operation, *p* = 0.009), and a 40% reduction in nonoperative procedural errors. Although these authors acknowledged the limitations in generalizing their results beyond their academic setting, their findings were consistent with the results obtained by Morey et al. [81] in their structured team training intervention for emergency department staff. Morey et al. in 2002 published findings of their prospective, quasi-experimental, multicenter trial of a systematic team training program intervention in the emergency room setting. They reported a significant improvement in team behaviors (*p* = 0.012) and significant reduction in observed errors (30.9%–4.4%, *p* = 0.039) in those departments participating in team training compared to controls. Significant improvement were also seen in staff attitudes toward teamwork (*p* = 0.047) and assessment of institutional support (*p* = 0.04).

SIMULATION-BASED TRAINING OF SURGICAL TEAMS

Simulation-based training and practice offers a viable means by which to promote safe practice and sharpen procedural and teamwork skills across the spectrum of inpatient and outpatient settings [82]. Formal training and deliberate practice of teamwork and procedural skills in simulated OR settings can obviate relying on the traditional apprentice approach. Human patient simulation is the medical simulation version of the simulator cockpit, employing an experiential learning model well suited to adult learners. Kolb and Fry [83] positioned four elements of experiential learning in a cycle: concrete experience, observation and reflection, formation of abstract concepts, and testing in new situations. Learners can enter at any point but most enter by means of a specific concrete experience in the context of a particular situation. Gaba incorporated this approach into his ACRM curriculum, allowing systematic presentation of a wide variety of routine and uncommon but critical events in a simulated medical setting [57]. Although there is no gold standard team training curriculum in healthcare, the IOM encourages team training programs such as CRM and simulation for personnel who work in critical care areas [84]. Medical simulation provides a vehicle by which clinicians can experience an event and reflect and learn in an atmosphere of safety, free of patient harm.

As per Gaba, medical simulation, practice, and drills never pose a risk to live patients [57].

Aggarwal and colleagues [85] further asserted in 2004 that practicing team skills enables surgical teams to function in a safer, more efficient manner when crises occur in real life. This was nicely illustrated in a study by Weaver et al. [86] who evaluated whether or not teamwork training improves performance in the OR. They compared a control group with an intervention group that was exposed to a medical team training curriculum, Team Strategies and Tools to Enhance Performance and Patient Safety, the next generation of MedTeams that was developed by the DoD in collaboration with the Agency for Healthcare Research Quality. The 4 hour curriculum included case-based interactive sessions and low-fidelity simulation for practice. Trainee reactions, learning, and behaviors were assessed, and team performance in the OR was observed, identifying the degree to which team training skills were enacted. They reported positive results in the intervention group compared to the control group in the quality of presurgical procedure briefings, use of high-quality teamwork behaviors during procedures, and perceptions of safety culture and teamwork attitudes.

Vincent et al. [87] strongly advocated for including team training as part of a broad-based systems approach to surgical quality and safety. They also strongly supported research aimed at optimizing the surgical environment, equipment design, and understanding subtleties of decision-making in the complex OR environment. Such broad-based efforts would include direct observations, including visual–audio recordings, assessment of surgical team performance, and the routine use of fully operating theater simulation targeting all members of the surgical team. Implementing such a system may be the most important intervention to enable surgical teams to achieve high performance and better outcomes for patients. To that end, Moorthy et al. [88] assessed technical and teamwork skills of two surgical teams managing a bleeding crisis during a simulated vascular procedure in a simulated OR. The event was videotaped and used to provide feedback in the immediate postscenario debriefing. Technical ability in controlling the bleeding was assessed with a global rating scale. Teamwork or “nontechnical” skills were assessed using a NOTECHS skills rating scale that was originally developed for aviation and adapted for use in healthcare. Additional metrics included evaluation of communication within the team, amount of time to complete specific tasks, and a surrogate outcome measure of the total (simulated) blood lost—amount captured in the canister and weight of blood-soaked sponges.

Participants also completed a questionnaire about their perception of the simulation experience. The investigators found that the simulated scenario was well received and deemed as realistic by the participants. Significant differences were seen between junior and senior trainees in managing the bleeding crisis, with seniors demonstrating quicker times for recognizing the crisis and instituting appropriate interventions. Junior trainees were more likely to blindly use and apply clamps to stop the bleeding and experience greater blood loss, and they were less likely to realize their limitations and call for help. There was utility in the variations found between and within groups, potentially for identifying and setting performance standards and guiding which trainees may need further assistance in skills acquisition and crisis management. NOTECH scores for teamwork did not differ significantly between the groups. The investigators postulated that the wide variability of scores within the groups may be related to the lack of focus on developing effective team skills in surgical training. The construct and content validity of the NOTECHS rating scale has since been evaluated and deemed a reliable instrument for assessing teamwork in the OR [89,90], and its use has expanded beyond the OR to trauma bays and surgical wards [91–93].

The current state of team training and its effectiveness in acute care settings was recently explored by Weaver et al. [94] They compiled a database of reviews having examined the effectiveness and implementation of team training and published between January 2000 and December 2012 and also included 26 additional primary studies about team training effectiveness on clinical processes or patient outcomes published between January 2011 and December 2012. Overall, they found moderate- to high-quality evidence indicating that team training, whether simulation or didactic based, has a positive impact on team processes and improved clinical process and patient outcomes in acute health-care settings, including critical care units, labor and delivery, surgery, and emergency care. They highlighted the study by Riley et al. [95], demonstrating significantly greater reductions in patient harm achieved by the simulation group compared to the didactic and control group. They also stressed that the greatest impact on patient outcomes was found in those studies [96–98] that had implemented team training as an intervention bundled with formal evaluation of readiness for such training and the use of interdisciplinary learning activities and tools that support transfer and daily use of teamwork skills. In particular, Neily et al. [96] reported an 18% reduction in annual surgical mortality, and Young-Xu et al. [98] reported a 15% decrease in hospitals in the Veterans Health System that had implemented a medical team training program compared to a 10% decrease in those that had not.

SURGICAL SIMULATORS FOR TECHNICAL SKILLS TRAINING

A variety of devices, ranging from simple to complex objects, cadavers, or animal models to elaborate virtual reality (VR) devices, have been developed for training and practice of surgical maneuvers and procedures involving the abdomen and pelvis [99]. These include knot-tying or suture placement trainers, pelvic exam training devices such as the Pelvic ExamSim™ (METI®, Sarasota, FL) that has internal sensors and software that feeds information back to the learner about their performance [100], and life-size human patient mannequins for simulating surgical scenarios in a simulated or real OR environment [101,102]. It is still not clear how much physical realism is needed for skills training and assessment of open laparotomy procedures involving major abdominal and pelvic organs, such as hysterectomy, vesicovaginal fistula repair, or vaginal vault suspensions. Video-simulation, VR, computer screen–based, or haptic systems may offer greater opportunities to enhance the realism and may be used in combination with human patient mannequin simulators [82,103]. The surgical robot system is revolutionizing surgical practice across a variety of specialties, including urology [104] and gynecology [105]. VR-assisted robotic surgery simulators are undergoing validation [106] and full simulations are being developed [107]. The total immersion in VR–haptic surgical environment, the “surgical holodeck,” remains an area rich for research and development [108–110].

The paradigm of surgical education and training continues to shift from the traditional “see one, do one, teach one” approach to that of “learn and practice on a simulator first.” Simulators are steadily being integrated into the surgical curriculum for training [111–113], assessment [114–116], credentialing [117–120], and reentry to clinical practice [121,122].

The integration of VR technology with endoscopic training devices was proposed by Satava in 1993 [123], and VR has since become integral to a broad range of surgical simulators. Box trainers and VR laparoscopic simulators have been shown to facilitate skills acquisition and training across the spectrum of novice to expert. Such training has translated into improved proficiency in the OR. Scott et al. [124] in 2000 evaluated global performance during laparoscopic cholecystectomy and found significantly higher scores among surgical residents who trained with box trainers than those who had not. Fichera and colleagues [125] in 2005 also noted statistically significant improvements in suture technique and coordination of trainees using the LTS 2000 laparoscopic box trainer. Seymour et al. [126] conducted a randomized, double-blind controlled trial evaluating VR simulator–based training and found improved performance of skills in the OR in those with such training. Similar findings were obtained by Gallagher et al. [127] and Grantcharov et al. [128] Laparoscopic skills have reportedly improved for novices who trained with either box or VR simulators. [129] Grantcharov et al. [130] conducted a randomized clinical trial of surgical residents using VR simulators. Surgical skills of residents who trained with the laparoscopic simulator directly translated into better performance in the OR. Even third year medical students rotating through gynecology and general surgery achieved proficiency whether they trained with laparoscopic box or VR simulators [131]. However, students training with laparoscopic VR simulators reached proficiency sooner than those who had not used them.

Aggarwal et al. [132] demonstrated that non-VR simulators can differentiate novice from expert. They evaluated the performance of novice and experienced gynecologists in a series of laparoscopic tasks needed for managing ectopic pregnancy. Novices significantly improved their surgical performance and experienced gynecologists demonstrated little change over time. Aggarwal and Darzi [133] showed that skills acquired using a VR simulator had high transferability to the porcine model, with every hour of training reduced by 2.3 hours, which is the time needed to gain proficiency. Demonstrating transferability to surgical procedures involving real patients and evaluating cost-effectiveness of such training will be an area of future research. Both Geoffrion [134] and Goff [135] showed simulation-based surgical skills training improved the technical performance of gynecology residents and such skills were translated well to the OR. They each underscored the need for standardizing simulator-based curriculum to consistently train and assess surgical care in clinical practice.

Kahol et al. [136] evaluated the potential role of surgical warm-ups, the preprocedure short-term practice sessions with a simulator, to exercise a surgeon’s psychomotor and cognitive skills. Kahol et al. conducted a series of experiments involving 46 surgeons that comprised of novice to senior gynecology and general surgery residents and attending trauma surgeons. The first experiment evaluated the impact of the warm-up on surgical proficiency and its relationship with experience, fatigue, and cognitive and psychomotor skills. The second evaluated whether basic skills warm-up improved performance of complex tasks. They found that regardless of the level of expertise, all surgeons benefitted from the surgical warm-ups as a 25%–45% range in reduction of error was noted. The time required to complete a task was substantially diminished. Warm-ups diminished cognitive errors ($p < 0.0004$) and improved performance in all parameters being studied in the fatigued individual. Even though performance improved in the fatigued individual, it did not return to baseline performance levels characteristic of the rested state. These findings suggest that the preoperative warm-ups may become a new surgical standard, assuring optimal care of the patient during surgery.

At that time, Satava predicted surgical simulation would steadily evolve and mature from its relatively infant to assume the breadth and scope of its use in the fields of aviation and the military [137,138]. In view of continued growth in the use of robotics in almost every surgical subspecialty and the evolution of robotic platforms, the continued use of simulation and telementoring to enhance surgical performance is thereby assured [139]. Indeed, preoperative simulation warm-up exercises on a VR robotic simulator have since been shown to significantly improve robotic surgery performance and reduce errors among surgeons, including general surgeons, urologists, and gynecologists, from experienced to novice [140].

Brewin et al. [141] recently reviewed simulation-based training from a urology perspective. They agreed that such training provides opportunities for surgeons to train without harming patients. They found good evidence that use of part task trainers shortens the learning curve, especially for newer trainees. They highlighted studies by Lee et al. [142] and Gettman et al. [143] whose findings supported the need for nontechnical skills training, and such training was possible in a high-fidelity simulated OR. Evidence they gathered in their review further bolstered the argument for formally incorporating simulation-based training of technical and nontechnical skills into a urology training curriculum.

CHECKLISTS

The use of checklists in surgical care has virtually exploded since the launch of the Universal Protocol in 2004 [144], a protocol aimed at preventing wrong-site-, wrong-patient-, wrong-procedure-related surgery, combined with the introduction of the WHO surgical safety checklist in 2008 [79]. Studies by Lingard et al. [145] and de Vries et al. [146] laid fundamental groundwork toward incorporating the use of checklists to improve communication among team members in the OR and facilitate safer care of the surgical patient. Lingard's team of researchers were particularly concerned with the impact of communication breakdowns in the OR, having previously identified communication failures in about 30% of procedurally relevant team exchanges of information [147], about a third of which jeopardized patient safety. They subsequently developed a checklist prototype and piloted its use in 18 vascular surgical procedures performed in Canada. Three researchers observed its use in real time, noting patterns of use. Their data indicated that a preoperative checklist could foster OR team communication about key information before a surgical procedure and facilitate team cohesion. Thereafter, Lingard and colleagues [148] conducted a 13-month prospective study to evaluate whether use of a checklist in preoperative briefings improved interprofessional team communication in the OR. Using a pre-/postintervention study design and trained observers, a total of 172 surgical procedures were observed. They found that the mean number of communication failures per procedure significantly decreased from 3.95 preintervention to 1.31 postintervention ($p < 0.001$). The checklist briefings revealed knowledge gaps, promoted learning, and triggered actions among members of the team. The investigators also appreciated the impact of a traditional silo approach of nurses, surgeons, and anesthesiologists working independently; staff shortages, educational demands, and economic pressures had on surgical workflow; and the potential for jeopardizing patient safety.

The surgical patient safety system ("SURPASS") checklist, developed by de Vries et al. [146] in the Netherlands, is a checklist whose design was based on a synthesis of human factors' literature and review of literature on surgical errors and adverse events. Items contained in their tool were validated with real-time observations in the OR and then introduced it into practice. All health-care providers involved with the patient along the surgical pathway were taught how to use the tool and complete their sections. SURPASS is comprised of five sections addressing the preoperative ward, OR, recovery room or ICU, postoperative ward, and time of discharge, thus serving as the first tool covering the entire admission to discharge pathway. The use of SURPASS was well received overall. However, some users did not complete the tool due to lack of consequences and some users strongly advocated for creating an electronic version and have it integrated with their hospital information system. The SURPASS checklist has since been shown to improve compliance with timing the administration of antibiotic prophylaxis [149] and was associated with a decrease in total number of complications from 27.3/100 patients prior to using the checklist to 16.7/100 patients after its implementation [150]. The latter study also showed in-hospital mortality, which decreased from 1.5% to 0.8% after implementation of the checklist, and no changes in outcome were found in the control hospitals who had not been exposed to SURPASS.

Bouchard et al. [151] conducted a systematic review of implementation of surgical safety checklists in 2012. Of about 5000 thousand articles published on this topic between 1995 and April 2011, they identified 22 for inclusion. Either the Universal Protocol, the WHO checklist, or a new protocol, based on either or both, was used in 17 studies, and 4 studies involved the use of SURPASS. At the time of their review, the Universal Protocol had been implemented in 2257 hospitals in the United States, WHO checklist had been implemented in 3000 hospitals among 25 countries, and SURPASS had been implemented in 16 hospitals in the Netherlands. Bouchard et al. found use of the checklist was associated with a relative risk for mortality of 0.57 and a relative risk of 0.63 for any complication. Overall compliance with using the tools ranged from 12% to 100% (mean 75%) and a range of 70%–100% (mean 91%) for the time-out. They deemed surgical safety checklists to be effective in decreasing mortality and morbidity, specifically the WHO and SURPASS checklists. High compliance was associated with involvement of multidisciplinary surgical staff in the process of development. Critical factors for successful implementation included explaining to staff why and how the checklist would be used, coupled with real-time coaching, feedback, audits, ongoing education and training, and support of hospital administrators and leaders.

Treadwell et al. [152] conducted an in-depth analysis of the impact and implementation of the Universal Protocol, SURPASS, and WHO surgical safety checklist. They reviewed 33 studies published between 2000 and 2012 and found checklists had been widely adopted worldwide and in diverse contexts, especially the WHO checklists. Checklists were associated with improved health outcomes such as decreased surgical complications and surgical site infections, increased detection of potential safety hazards, and improved communication among members of the operative team about relevant and important information about the patient. They confirmed that successful implementation of checklists involved factors such as administrative and leadership support, training staff on their use, adapting the checklist to incorporate staff feedback and avoid duplicate efforts in data collection. Barriers to effective implementation included confusion about practical use, managing workflow efficiently and the beliefs and attitudes of staff, especially surgeons, toward checklists. A concept central to all three checklists is that they are tools by which to encourage team-based interactions among multidisciplinary OR staff. The surgical safety checklist provides an opportunity for every team member to speak up and offer up information of concern, allowing everyone involved to be on the same page and situationally aware of what to expect. The extent to which such teamwork contributes to the impact of the checklist and the extent to which patients should be included are rich areas for research.

DECISION-MAKING AND DIAGNOSTIC ERRORS

Identifying evidence-based methods that facilitate effective decision-making and reduce diagnostic errors is the new frontier for patient safety [153]. Leape et al. [154] categorized medical errors into four types: diagnostic, treatment, prevention, and others (including communication or system related). Diagnostic error includes delayed, missed, or wrong diagnosis, failure to use indicated tests, and failure to act on the results of monitoring or testing. Berner and Graber [155] noted that such errors occur in every specialty, ranging from 2% in perceptual specialties (such as radiology and pathology) to as much as 15% in the clinical specialties. Their review of the literature led them to conclude that overconfidence, a trait of human nature, does exist among physicians. Such overconfidence contributes to diagnostic error. Physicians believe that diagnostic error exists but underestimate the likelihood of their occurrence, especially in their own decision-making processes. This is evident in physician disregard for decision aids or tools or diagnostic or treatment guidelines or algorithms. If a clinician is uncertain about a clinical situation, then formal or informal consultative assistance is more likely to be requested, especially when the case is complex. However, Berner and Graber believe most cognitive errors arise when cases seem to be routine and physicians are certain about the decisions they have made.

Newman-Toker and Pronovost [153] define misdiagnosis-related harm as preventable harm resulting from delay or failure to treat a condition that is actually present or to treat a condition that does not actually exist. Diagnostic errors are frequently not recognized and underreported and methods for detecting them are lacking. Such errors are often classified as cognitive errors rather than systems errors, a perspective that facilitates attribution of individual blame. Newman-Toker and Pronovost suggest a different approach, taking a 5-point action plan that includes (1) developing systems such as computer-based decision support systems to facilitate cognition, (2) grouping errors based on clinical context rather than cognitive defect, (3) emphasizing misdiagnosis-related harm instead of diagnostic error, (4) taking a systems approach to improving workflow, and (5) building cost-effective diagnostic tools or decision aids that may not be perfectly accurate but assist the human mind.

Medical decision-making involves a series of cognitive steps from outlining the goal and desired outcome, gathering the data, evaluating choices and alternatives, considering pros and cons to each, making the decision, implementing the decision, and learning from the decision. Most diagnoses are clear and unambiguous. However, when a situation is uncertain, complex, and time pressured, then major decisions are frequently made rapidly and subconsciously and bypass the cognitive steps. Such rapid decisions are highly influenced by biases of prior experience and memory, unconscious reasoning, and intuition [156]. Croskerry et al. [157] contend that humans spend about 95% of their time behaving intuitively. Judgments and decisions arising are aided by heuristics—mental rules, rules of thumb, maxims, or shortcuts—that allow one to size up and manage a situation rapidly. Croskerry [156] grouped biases and failed heuristics under the term “cognitive disposition to respond” (CDRs), removing the stigma of bias and clearing the way to accept the “capricious nature of decision-making.” He identified at least 30 CDRs and contended there were probably more. Fargen and Friedman [158] more recently identified that a subset of CDRs that they found were applicable to neurosurgeons. These are generally applicable to surgeons (see Table 10.4).

There are strategies to facilitate “cognitive debiasing,” a term coined by Croskerry et al. [157,159], referring to controlled analytic thought processes to overcome biases, the so-called cognitive pills for cognitive ills [156]. Educational strategies can help improve future decision-making such as learning about cognitive bias and its impact on medical decision-making, being aware of one’s own biases, and training in techniques for overcoming bias, including use of simulation-based training. Simulation of diagnostic error-related cases offers safe and practical means by which to better understand the factors contributing to cognitive error in contextually relevant settings and identify solutions for preventing or mitigating their effect [160]. Likewise, simulation is a practical and safe means by which to assess the efficacy of diagnostic and decision support interventions before they are implemented on a system-wide basis in the clinical setting. Workplace strategies for cognitive debiasing can help facilitate decision-making in the moment of problem-solving. These strategies include slowing down activities such as procedural time-outs or diagnostic time-outs, taking time to pause and reflect on the working diagnosis and supporting evidence, gathering more information, deliberately being more skeptical, seeking other’s opinions, and recalibrating one’s perspective. Force function strategies for cognitive debiasing also facilitate clinicians’ ability during the moment of problem-solving to consciously consider alternatives, thereby mitigating error. These strategies include the use of cognitive aids, checklists, algorithms, practice guidelines, protocols or similar tools, and the technique of deliberately taking time to rule out the worst-case scenario or intentionally consider a diagnosis opposite to the initial impression.

Table 10.4 Cognitive Dispositions to Respond: Applicable to Surgeons

Cognitive disposition to respond	**Description**
Anchoring	Tendency to weigh initial data too heavily and failure to adapt the diagnosis once more information is available, sticking with the diagnosis.
Availability bias	Tendency to judge diagnosis more likely if one has been recently seen or experienced.
Commission bias	Tendency to promote patient beneficence through action rather than inaction, performing a treatment or procedure because the patient is ill.
Confirmation bias	Tendency to look for evidence that confirms a diagnosis rather than look for evidence to refute.
Diagnosis momentum	Tendency to label a diagnosis for gaining traction with the patient and health-care workers so that it is perceived as definite rather than possible.
Fundamental attribution error	Tendency to blame patients for their situation or illness rather than examine their actual circumstances.
Hindsight bias	Being aware of the outcome influences the perception of past events such that the role of an individual is under- or overestimated.
Omission bias	Tendency to avoid doing something wrong through inaction rather than action.
Order effects	Tendency to remember the beginning and end during information transfer, neglecting data exchanged in the middle.
Overconfidence bias	Tendency of an individual to believe themselves to be more knowledgeable than they really are, leading to action based on inadequate information or intuition without appropriate supporting evidence.
Premature closure	Tendency to accept a diagnosis as true before it has been fully verified.
Search satisfying	Tendency to stop looking for other problems once one is identified, leading to missed diagnosis or injuries.
Visceral bias	Tendency to have decisions influenced by an emotional or affectively labile state; countertransference, negative or positive feelings toward a patient, leading to missed diagnosis or injuries.

DISCLOSURE AND APOLOGY OF ADVERSE EVENTS AND ERRORS

Since errors are inevitable wherever humans are involved, surgery-related errors and adverse events will happen. Methods for managing their aftermath should ensure information is fully disclosed to patients and their families and preserve trust in the patient–doctor relationship and action will be taken to help prevent recurrence of similar errors. Just as the paradigm of surgical education and training has shifted from an apprentice model to one of the simulation-based learnings and practices, health-care education and specialty training have come to appreciate the importance of formally teaching trainees techniques of effective communication and how best to manage difficult conversation and apologize to a patient who has experienced harm due to errors and adverse events. Disclosure has come to be seen as an integral component of patient-centered care and elemental in promoting quality and safety of healthcare [161]. The Joint Commission stepped forward in 2001 to set standards for disclosing unanticipated outcomes of patient-related events by the provider or institutions [162]. The Patient Safety and Quality Improvement Act of 2005 [163] established a confidential, voluntary system in the United States for clinicians to report adverse medical events. Health-care institutions in the United States and worldwide have since established or are instituting policies for such disclosure and incident reporting systems to capture information about adverse events and near misses [164–166].

Disclosure is telling patients important information about their medical care or condition that affects or has the potential to affect their current or future well-being. The physician is expected to conduct the conversation but may be accompanied by other members of the team, or there may be occasion for some other team member to lead the discussion. Patients prefer to know about unanticipated outcomes and adverse events that may have occurred [167]. Kaldjian et al. [168] identified a gap between physicians’ attitudes toward disclosure and what they practice. Surveys sent to physicians, residents, and medical students in the Northeast, Mid-Atlantic, and Midwest of the United States revealed that 97% of responders would disclose a hypothetical error resulting in minor harm and 93% would disclose a hypothetical error resulting in major harm to patients. However, 41% of responders had disclosed an actual error involving minor harm, and only 5% had disclosed an actual medical error involving major harm/death or disability to a patient. These results indicated a discrepancy between the willingness to disclose medical errors and the actual disclosure of errors by physicians. Waterman et al. [169] investigated the impact of medical error on physicians in the United States and Canada. They reported that physicians experienced anxiety about future errors, loss of confidence, difficulties sleeping, and some feared damage to their reputation. Barriers to disclosure include psychological issues such as the fear of retribution from the patient and colleagues; fear that conversations won’t go well; fear of the emotional impact to the patient and self; and beliefs that disclosure is unnecessary, that the unanticipated outcome would have happened anyway, and that the outcome is not directly related to the clinician’s actions. Legal barriers to disclosure include lack of legal protection about the information conveyed, lack of clarity about what needs to be disclosed and when, and belief that disclosing will not be beneficial if case becomes a malpractice claim. However, from the ethical perspective, patients have a right to know about what happened. Disclosure of unanticipated outcomes, adverse events, or near misses is the ethical imperative. Furthermore, Leape stresses the therapeutic aspects of disclosure, stating that full disclosure is essential for healing for the patient, the patient–doctor relationship, and the clinician involved [170]. Surgeons face unique challenges to providing full, appropriate disclosure of surgical adverse events to patients due to the high frequency of such events, current structure of the medicolegal system and variability in legal protections, team structure of surgical care, and lack of clear, reasonable, and specialty-specific standards for guiding disclosure in surgery [171]. Strategies for improvement include training and coaching for disclosure conversations, providing organizational peer support programs and resources for clinicians, improving clinicians’ understanding of the relationship between disclosure and litigation, and establishing organizational programs for communication and resolution, coupled with patient compensation when indicated. Additional strategies offered by Lipira and Gallagher [171] include facilitating collective accountability for individuals and systems in taking responsibility for disclosure conversations, participating in measures to understand why the adverse event happened and how to prevent its recurrence, and establishing standards for disclosure by surgical specialty and subspecialty professional organizations.

Much progress has been made over the past two decades toward better understanding the need for transparency with patients about medical errors and adverse events, yet challenges remain in putting policies and procedures into practice [166]. Even countries known for having supported disclosure on a national level are still challenged by (1) putting policy effectively into large-scale practice, (2) managing conflicts between patient expectations and patient safety theory, (3) resolving conflicts between open disclosure and legal privilege and protections, (4) aligning open disclosure with compensation, and (5) effectively measuring the occurrence of disclosure and its quality. Much remains to be done to overcome these challenges and advance the patient safety agenda.

Apology is the expression of regret or remorse for the unanticipated outcome, adverse event, or near miss. Apology shows the humanity and fallibility of clinicians, a therapeutic necessity for healing and making amends [170]. Lazare [172] in 2006 stated that an effective apology should (1) acknowledge the offense, (2) explain the commitment of the offense, (3) express remorse, and (4) offer reparation for the offense. Properly conveyed, the apology should touch on all these elements and be relayed with sincerity, preserving the patient's dignity and providing reassurance that the clinician cares about the patient's well-being. Performed this way, such apologies facilitate the healing process. Cravens and Earp [173] in 2009 highlighted the following "five R's" and "five A's" for guiding effective disclosure and apology (see Table 10.5).

Table 10.5 Five "R's" of Apology and "A's" of Making Amends

Five "R's" of apology	
Recognition	Understand the patient's feelings and your feelings, the basis for them, and recognize when apology is in order.
Regret	Respond with empathy; acknowledge the patient's feelings. Tell them you regret what they are experiencing. Apology does not imply guilt.
Responsibility	Take responsibility for what happened and disclose all the details that led to the outcome.
Remedy	Make clear to the patient what is being done to remedy the situation, including financial costs or compensation if appropriate.
Remain engaged	Continue to provide care for your patient after the outcome, reassuring them you will remain engaged and available.
Five "A's" of making amends	
Accurate	Truthfully and accurately tell the patient that an error has occurred.
Answers	Anticipate the patient's needs for answers about the error and what impact it may have on their clinical situation.
Accountable	Explain what is known about how the error occurred and accountable about future actions taken to prevent similar errors from occurring.
Apology	Apologize to the patient for the error.
Acknowledge	Acknowledge the patient's responses about the error and its occurrence, addressing their concerns as they arise.

Source: Adapted from Cravens C and Earp JL, *NC Med J*, 70(2), 140, 2009.

A genuine apology can go a long way toward defusing a patient's anger, showing them respect and empathy, and further facilitate the healing process for all involved. Legislative initiatives that provide legal protection for disclosure and an expression of sympathy or full apology have been drafted or passed, varying in scope and breadth from region to region worldwide [166]. Pelt and Faldmo [174] reported in 2008 that 35 states within the United States had enacted apology statutes and 3 had legislation pending. They regarded such statutes as still in their infancy and unclear as to how well they would stand up in court. Since then, Saitta and Hodge [175] published in 2012 that 34 states and the District of Columbia had enacted laws prohibiting a physician's apology with disclosure from being admissible evidence in legal proceedings. They highlighted emerging evidence from Michigan [176], Colorado [177], and Kentucky [178] that apologies have reduced the cost of litigation per claim since the implementation of an apology and disclosure program. They emphasized the importance of being aware of the statutes applying to a specific jurisdiction and practice location because the laws of each state have their own nuances. One's own institutional risk managers can provide guidance and help clarify what to say and when and how best to proceed.

SUMMARY

Ensuring safety and quality is the responsibility of every member of the surgical team. Achieving a balance of expert knowledge, technical skills, sound decision-making, and optimal teamwork behaviors offers the best approach toward assuring reliably safe, high-quality care of our surgical patients. As surgeons, we aspire to provide the safest, highest-quality health-care services. The literature reviewed here underscores the importance of a patient safety culture and supports surgical teamwork training and simulation for practicing routine and critical procedures and events, improving technical proficiency and team interactions, and error reduction, recognition, and management. The paradigm of surgical education has indeed shifted from the apprenticeship style of learning. More research is needed to advance our understanding of what environments best facilitate excellence in training and proficiency in technical and teamwork skills, skills that are translatable to the surgical arena. Sound educational objectives serve as the best guide for the ongoing development of simulator technology and the extent of its realism and fidelity. This chapter identified several ways by which to prevent medical errors or mitigate their effects given that all human beings are subject to making errors. Effective disclosure and apology is vital to the process of error management. A thorough understanding of where surgical practice is vulnerable to error best informs design of systems-based approaches to mitigate the clinical demands that weaken our defenses and facilitate provision of the safest, highest-quality surgical care for our patients.

Section II

Role of Patient Reported Outcome Measures and Health Economics

11

Section Introduction: The Role of Patient-Reported Outcome Measures and Health Economics

Cornelius J. Kelleher

Understanding the patient perspective of any medical condition allows us to treat our patients more effectively, compassionately, and completely. Lower urinary tract dysfunction and genital prolapse can be described by objective investigations and clinical examination. Treatment outcomes can be assessed in a similar manner. Ignoring the patient perspective can, however, lead to inappropriate conclusions regarding treatment desire, appropriate treatments to select, and treatment efficacy. How conditions affect patients' lives and how they hope to benefit from interaction with the medical world can only be answered by the patients themselves. This chapter hopes to discuss our current understanding of patient-reported outcomes (PRO) assessment.

In Chapter 12, Coyne and Sexton introduce the concept of patient-reported outcomes, from their development through their selection and usage for clinical trials and clinical practice. In this chapter, the authors describe the evolution of the PRO to encompass many aspects of the patient pathway, from the initial assessment of the symptoms and the bother they cause to the multifaceted assessment of treatment outcome. Increasingly, the patient perspective of treatment success is recognized as the most important goal of medical interventions. Whether the patient is satisfied with their treatment, whether it improves their symptoms sufficiently, and whether they wish to persist with treatments outside the context of clinical trials are all hallmarks of a successful intervention. The authors describe how the bother caused by a problem can be addressed and measured in a reproducible way and how to select the best tools to use in various different settings.

In Chapter 13, the individual questions used to measure the quality-of-life outcomes of patients with lower urinary tract dysfunction are described in greater detail. Understanding as much as possible about the content of the questionnaire, its previous usage, size, etc., ensures that the correct tool can be chosen for the correct purpose.

Kopp and Evans focus on patient satisfaction, expectations, and goal achievement in Chapter 14, a new edition to this volume of the textbook. It is now increasingly recognized that setting realistic patient goals and expectations for treatment are of paramount importance to satisfactory treatment outcome. Addressing patient goals before an intervention supports dialogue with a patient and ensures that they understand what a treatment is likely to achieve and helps the clinician understand what a patient would like the treatment to do. This is a very important chapter and highlights the fact that clinicians and patients are not always on the same wavelength regarding the expectation of an intervention and what signifies treatment success. How to measure goals and patient satisfaction has evolved considerably, and while we all undoubtedly address various aspects of this in our clinical practice, how best to do it and what instruments are available to do it properly may not be so clear.

In Chapter 15, Domoney and Symonds have updated their chapter from the previous edition of this textbook to include new questionnaires to assess sexual function. The assessment of sexual function in a standardized fashion is crucial to understand the problems that patients are experiencing, and whether treatments impact positively or indeed negatively on this important aspect of their lives. So many of the problems affecting the lower genital and urinary tracts impact on sexual function, and so often it is assumed that treatments improve it. Without being able to measure it in a reproducible and meaningful way, we are unable to draw these conclusions. This is a must-read chapter that will complement chapters one to three.

In Chapter 16, Mohamed, Chatoor, and Williams describe questionnaires used to assess bowel function. Many patients with lower urinary tract dysfunction and genital prolapse have associated bowel symptoms. Increasingly, we are working as part of a multidisciplinary team to assess and treat all aspects of a patient's concerns from the outset. The inclusion of clinicians trained in the clinical assessment and treatment of lower bowel dysfunction is recognized as well as the use of questionnaires to identify bowel problems as part of the initial patient evaluation. Specific tools for this purpose have evolved along a similar pathways to those used to measure lower urinary tract dysfunction. Currently, available questionnaires are discussed in this chapter.

In Chapter 17, further evolution of the International Consultation on Incontinence (ICI) modular questionnaire is described by Cotterill and Abrams. This chapter should be useful when designing a study or clinical trial. Many of the questionnaires adopted by the ICI appear in various other chapters of this book and several have been specifically designed by the ICI when suitable tools were not available elsewhere. The idea of a modular questionnaire is essential to the assessment of the many different aspects of the typical conditions that we see and treat. The chapter guides the reader through selection of the recommended instruments in order that the best tool for each desirable outcome can be used with as little overlap of the tools as possible.

Increasingly, we are living in an electronic world where paper is replaced by computers and keypads. While not all of our patients are computer literate and the expense of computerized assessment not always affordable, questionnaire completion has moved into the computer age. Radley and Gopinath, in Chapter 18, describe the ePAQ questionnaire as one of the leaders in this field. The ePAQ can be used as a self-completion tool to reduce clinician workload in initial assessment as well as measure outcomes in clinical practice and clinical studies. Progress is always important and I suspect in the coming years we will be losing our paper notes and the computer era will be upon us. Ultimately, the inclusion of many of the questionnaires already discussed in this section will be amenable to computerized completion and scoring, which is already the case in many clinical trials.

Prolapse questionnaires have evolved considerably over the last decade, possibly in response to the huge interest in new ways to treat this condition. The last decade witnessed an explosion in the use of mesh kits to treat prolapse and a subsequent and almost as rapid decline as fear over complications arose. Understanding how and whether patients are bothered by their anatomically demonstrable prolapse has allowed us to reevaluate the success of our prolapse surgery. The fact that patient satisfaction after prolapse surgery does not always correlate with anatomical correction will allow us to better understand what patients want from surgery and avoid the pitfalls of treating anatomical defects rather than patient’s symptoms and expectations. In Chapter 19, Digesu describes questionnaires currently available to assess patients with prolapse in the hope that we can better understand the patient perspective of this common condition.

Chapter 20, the final chapter in this section, discusses the important aspect of health economics. Having recently witnessed a world financial recession at the same time as an ever-increasing expectation of successful healthcare, we need to be certain that our treatments are cost-effective and affordable. It is not always the most expensive option that is the best, and sensible rationing to achieve as much as possible for as many as possible is the key to sensible management of our health-care budgets. In this chapter, Moore offers an interesting insight into financial conundrums in healthcare and describes the terminology and processes to allow us to better understand how they pertain to our own medical management decisions.

Hopefully, the reader will find this section both useful and informative. Inevitably, there are some areas of overlap but wherever possible these have been minimized. By reading this section, you will be in a better position to understand questionnaire usage, selection, and analysis, both in your clinical practices and clinical studies and trials.

12 Patient-Reported Outcomes: From Development to Utilization

Karin Coyne and Chris Sexton

INTRODUCTION

A patient-reported outcome (PRO) is any report coming directly from patients, without interpretation by physicians or others, about how they function or feel in relation to a disease or treatment [1,2]. The field of PRO research has evolved considerably over the last 30 years from an initial focus on quality of life (QOL) to a more multifaceted study of different aspects of disease and therapeutic impact with a comprehensive theoretic framework, accepted methods, and diverse applications [3]. As medical treatments have progressed from lifesaving benefits to QOL-improving benefits, PROs have become increasingly important to patients and health-care providers.

Traditionally, the clinical history has been used to gain a summary view of the symptoms patients experience; however, clinical histories often do not assess patient impact or patient perception of their condition. As such, patient-administered PRO measures have increasingly been used to support the clinical history and provide information about outcomes patients consider important. By facilitating comparisons of treatments in the context of research and routine clinical care, PROs can help patients and clinicians make better decisions about treatment and may even reshape how health care is conducted [4]. The science of developing and validating such PRO measures is the focus of this chapter.

In providing a method for the standardized collection of data or an objective assessment of a subjective phenomenon, PROs represent the most important clinical review of the patient experience of a condition, disease, or set of symptoms. In the clinical setting, PROs can be used to inform clinicians' and patients' decisions about treatments [5,6]. In the context of research and clinical trials, PROs can serve as a primary efficacy or key secondary endpoint in order to evaluate treatment effects from the patient perspective [2,7].

Importantly, patients' perceptions of outcomes associated with urogynecological health are greatly influenced by their personal beliefs about their condition and their understanding of the availability of various treatments [8]. Assessment of patient goals may be useful to patients and their clinicians in determining treatment options. For example, women with pelvic floor dysfunction who undergo treatment have been shown to have a variety of desired subjective goals that relate to their short- and long-term treatment satisfaction [9].

PROs are especially valuable in assessing symptoms that may be bothersome but cannot be fully assessed without direct report from the patient, such as pelvic floor disorders, urinary symptoms, fatigue associated with gynecological cancer, and aspects of bowel and sexual function. The use of PROs in the measurement of urogynecological health can help provide a context for what is driving treatment-seeking behavior and inform decisions about treatment options. Although urogynecological symptoms perceived by the patient or caregiver or partner do not necessarily translate into a definitive diagnosis [10], the quantification of symptoms and their impact coupled with observations in the clinical setting can be used to better consider treatment options and to assess treatment outcomes. This chapter will provide an overview of the types of PRO measures and review the PRO development and validation process from a scientific and regulatory perspective.

TYPES OF PATIENT-REPORTED OUTCOMES

Generic and Condition-Specific PRO Measures

PRO measures generally fall into two broad categories: generic and condition specific. Generic measures are designed to assess outcomes in a broad range of populations (e.g., both healthy and ill individuals). These instruments are generally multidimensional and tend to assess the physical, social, and emotional dimensions of life. An example of this type of instrument is the Medical Outcomes Study SF-36 Health Status Profile [11].

Condition-specific measures are designed to assess the impact of specific diseases or conditions and include items more specific to the particular condition or population being studied. Condition-specific measures can be similar to generic instruments in that they assess multiple outcome dimensions. Examples of frequently used condition-specific instruments in gynecology and urogynecology include the Functional Assessment of Cancer Therapy-Ovarian [12], the Pelvic Floor Impact Questionnaire [13], the Incontinence Impact Questionnaire, the King's Health Questionnaire (KHQ) [14], and the Overactive Bladder Questionnaire (OAB-q) [15]. In general, there has been a growing trend to include condition-specific outcome measures in the clinical trial and research setting due to their enhanced sensitivity to change and the need to minimize participant burden.

Importantly, the type of measures selected for inclusion in a research study will depend on the goals of the intervention and the specific research questions to be addressed. Important considerations about the instrument include what is being measured (concept and form), who is being assessed (target population), when the assessment is occurring (study design and frequency of assessment), and how it is being administered (mode) [7]. In practice, clinical trials that include PROs usually incorporate a combination of PRO measures most relevant to the study population and intervention and prioritize the selection of these instruments according to the resource constraints and staff and participant burden. In the clinical setting, PROs can be used to provide information about symptoms of disease to aid physicians in selecting therapies.

CLASSIFICATIONS OF PATIENT-REPORTED OUTCOMES

The term PRO is often used to refer to a number of different aspects of patient-based assessment. It is important to distinguish between the concept being measured, the instrument used to assess the concept, and the outcome as analyzed in a clinical trial or "endpoint" [2]. For example, when assessing urogenital pain in relation to sex, urogenital pain intensity is the concept, decrease in pain intensity is the outcome, and change over a certain time interval in pain intensity (as represented by a 10 cm visual analog scale) is the data point that is used in the statistical analysis.

As shown in Figure 12.1, outcomes that can be assessed directly from the patient frequently overlap. The most broad category is the health-related quality of life (HRQL), which, at a minimum, measures physical, psychological (including emotional and cognitive), and social functioning. Examples of urogynecologic-specific HRQL measures were provided earlier. Outcomes that frequently overlap with HRQL include the experience and frequency of symptoms (e.g., pain, urinary incontinence [UI]), the bother and discomfort associated with these symptoms, the impact of symptoms on activities of daily living (ADLs), the treatment satisfaction, and the cost considerations, such as work productivity, cost, and quality-adjusted life-years (QALYs). A brief description of each of these outcomes, with examples of instruments used in urogynecology, is provided in the following text.

While some outcomes are specific to a therapeutic area, other measures of physical and mental health and social functioning may be relevant across diseases. The National Institutes of Health Patient-Reported Outcomes Measurement Information System (PROMIS) is a cooperative group of research centers that conducts qualitative and quantitative research to create domain-specific measures of physical, mental, and social health for use across diseases [16]. Many of these conceptual frameworks and item banks have the potential to be useful in areas of urology and urogynecology. For example, qualitative research with women with UI suggests that while many of these existing PROMIS domains are relevant to UI patients, additional domains are needed to improve the comprehensiveness of these assessment frameworks [17].

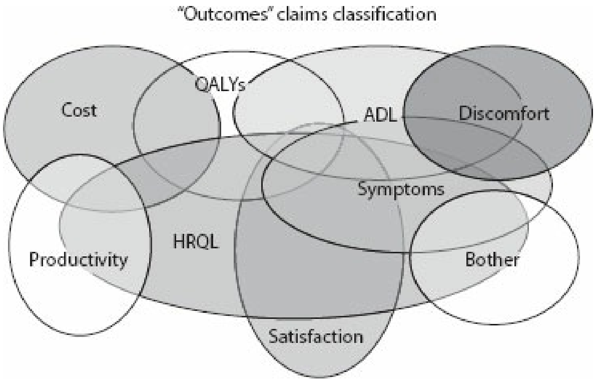

Figure 12.1 Patient-reported outcomes assessment areas. (From Burke L, Evidence Review Branch DDMAC, FDA, *DIA Workshop on Pharmacoeconomic and Quality of Life Labeling and Marketing Claims*, New Orleans, LA, October 3, 2000.)

Symptom Frequency and Bother

As stated previously, many symptoms in urogynecology are best understood based on direct report from the patient. For example, symptoms are defined by the International Continence Society as "the subjective indicator of a disease or change in condition as perceived by the patient, caregiver or partner and may lead him/her to seek help from health care professionals" [10]. Instruments designed to elicit patient-reported symptoms can assess a number of different dimensions, including presence/absence, frequency (e.g., how often patients experience a specific symptom; e.g., Pelvic Floor Distress Inventory [PFDI-20]) [18,19], and severity or bother (e.g., the symptom bother scale of the OAB-q [15] and the Urogenital Distress Inventory [20]).

Discomfort and Activity of Daily Living

Discomfort and/or pain are common outcome measures for many therapeutic areas. As such, measures of pain or discomfort are typically adapted from other generic measures (e.g., Brief Pain Inventory [21,22]) for specific urogynecology conditions. ADLs (e.g., the ability to dress and feed oneself) are infrequently assessed within urogynecology as such concepts, if pertinent, are incorporated into condition-specific HRQL measures.

Treatment Satisfaction

Patient satisfaction of treatment is the subjective, individual evaluation of treatment effectiveness and/or the service provided by the health-care system. At its most basic level, satisfaction is a comprehensive evaluation of several dimensions of health care based on patient expectations and provider and treatment performance. Measures of satisfaction can include evaluation of accessibility/convenience, availability of resources, continuity of care, efficacy, finances, humaneness, information gathering and giving processes, pleasantness of surroundings, and perceived quality/competence of health-care personnel [23]. As an outcome measure, patient satisfaction allows health-care providers to assess the appropriateness of treatment according to patient expectations. In chronic diseases, where patients must continually adhere to treatments, patient satisfaction may be the distinguishing outcome among treatments with comparable efficacy [24]. Two examples of patient satisfaction outcome measures that have been used in urogynecology are the Benefit, Satisfaction, and Willingness to Continue (BSW) measure [25] and the Overactive Bladder Satisfaction (OAB-S) measure [26,27]. The BSW is a single-item overall satisfaction measure, whereas the OAB-S is a multi-item, multidomain satisfaction measure. Another commonly used generic treatment satisfaction tool is the Treatment Satisfaction Questionnaire for Medication (TSQM) [28]. Generally, responsiveness cannot be assessed in this domain as there is no baseline assessment of patient satisfaction with treatment as no treatment has been given.

Productivity

The assessment of work productivity is particularly relevant for conditions that impact patients in their working years (<65). Currently, there are no condition-specific PROs for work productivity for urogynecological conditions; however, generic measures, such as the Work Productivity and Activity Impairment (WPAI) [29], are typically adapted to the specific patient population (e.g., the WPAI: irritable bowel syndrome) [30]. Productivity impact is an important construct to measure; however, there are many cultural and gender considerations in assessing this construct. Particularly notable is the complexity surrounding the assessment of productivity for those who work in the home but are not currently employed—a heterogeneous group predominantly composed of women and older people.

Cost and Economic Assessments

Cost and economic assessments are not necessarily PROs as many cost evaluations are conducted using currently existing economic data and claims databases. However, cost data are occasionally collected from patients to obtain cost information that is relevant to the patient (e.g., costs paid by the patient such as UI pads). The key to obtaining cost data from patients is to ensure that the questions asked are clear, easy to read, and understandable. Additionally, other relevant cost information must be collected as needed from other sources (e.g., claims databases) to fully evaluate economic impact.

Quality-Adjusted Life-Year

Increasingly, HRQL outcome measures are being used in the development of QALY measures. A QALY is a universal health outcome measure applicable to all individuals and all diseases, which combines gains or losses in both life quantity (mortality) and life quality (morbidity) and enables comparisons across diseases and programs. QALYs are widely used for cost–utility analysis [31]. In the past decades, economic evaluation has been increasingly important for the decision maker to decide which treatment or intervention is more cost-effective in order to allocate limited health-care resources soundly. The aim of economic evaluation is to compare interventions in terms of their costs and benefits, including their patient outcome impact. Health benefits can be quantified as QALYs, which has become a standard measure and is now recommended in most of health economics guidelines as the method of choice [32]. For example, algorithms have been derived to convert the OAB-q and KHQ to QALYs [33,34].

Conceptual Congruency

As described earlier, there are a variety of PRO instruments that differ in underlying construct measured. Thus, an essential component of selecting a PRO is to ensure consistency with the clinical purpose and objectives of the study. For example, if the goal is to assess treatment satisfaction, then a treatment satisfaction measure must be incorporated into the study design as a PRO. The matching of appropriate PRO selection with one's desired outcome is critical to success when assessing PROs.

PRO QUESTIONNAIRE DEVELOPMENT AND VALIDATION

To ensure that the results obtained with PROs are clinically useful, data must be gathered using valid and reliable instruments. The development of a PRO is a rigorous, scientific process designed to provide confidence that the PRO is measuring what it is intended to measure, that it does this reliably, and is appropriate for use in the patient or population group under investigation. The process begins by determining the intent and purpose of the PRO and culminates in studies that demonstrate the measure's validity, reliability, and responsiveness in the intended patient population. A task force for the International Society for Pharmacoeconomics and Outcomes Research (ISPOR) has developed a description of recommended research practices to establish content validity of newly developed PROs [35,36]. The specific steps required for developing a PRO questionnaire based on these recommendations and guidelines issued from the FDA are outlined in Figure 12.2.

Determining Questionnaire Intent and Purpose

The first task in developing a PRO measure is to determine why a new outcome measure is needed. Given the current number of disease-specific questionnaires available in the field of incontinence and related pelvic disorders, a new PRO measure must fill a need that has not already been met by an existing instrument. Once the need for the measure is recognized, its purpose and clinical usefulness need to be considered in order to inform the validation design. For example, a symptom measure would be developed and validated differently from a treatment satisfaction measure because of the different concepts evaluated by these outcomes.

The development stage would focus on the outcome of interest (e.g., symptoms patients experience and the significance of each symptom, or what issues patients consider when determining how satisfied they are with the treatment), with the items derived directly from patient statements and relating to the outcome of interest.

Developing Items and Assessing Content Validity

Designing a clinically useful PRO measure involves more than just developing a series of questions. In addition to obtaining clinician input and reviewing the literature to better understand the disease, questionnaire items should be developed based on carefully planned qualitative research with patients [35–37]. Qualitative research is critical to documenting the content validity of an instrument. Content validity refers to the qualitative assessment of whether the questionnaire captures the range of the concept it is intended to measure among the patient population for which it is intended [38]. For example, does a measure of symptom severity capture all the symptoms that patients with a particular condition have, and if so, is the measure capturing the items in a manner meaningful to patients? To obtain content validity, patients (and clinical experts to some extent) review the measure and judge whether the questions are clear, unambiguous, and comprehensive [7].

• Ability to detect change
• Minimum important differences

Figure 12.2 The development of a patient-reported outcome is a multistep process. (From FDA, Guidance for industry: Patient-reported outcome measures: Use in medical product development to support labeling claims, FDA, Silver Spring, MD, 2006.)

Patrick et al. [35] have outlined five steps to elicit concepts for a new instrument: (1) determine the context of use, (2) develop the research protocol for qualitative concept elicitation and analysis, (3) conduct the concept elicitation interviews and focus groups, (4) analyze the qualitative data, and (5) document concept development and elicitation methodology results (Table 12.1).

Table 12.1 Example of Saturation Grid

Stress urinary incontinence symptoms	**Group 1**	**Group 2**	**Group 3**
Leak urine while coughing	×		×
Leak urine while laughing	×		
Leak urine when sneezing	×	×	×

Leak urine when lifting something	×	×

Notes: No new concept emerged after Group 2; conceptual saturation for this set of concepts is demonstrated; the highlights indicate that the new concept was spontaneously mentioned, rather than probed about.

Qualitative research methods typically involve focus groups, semi-structured one-on-one interviews, and cognitive interviews [1,37,39]. Focus groups, which typically involve six to ten people with a common attribute, such as a disease, can have advantages over individual interviews in that descriptions of the patient experience are enriched by participants' responses to the comments of others [7]. Conversely, personal or sensitive topics may be better suited for one-on-one interviews or gender-specific groups. Focus groups and one-to-one interviews should be conducted by moderators with experience in qualitative methods, following a semi-structured interview or discussion guide.

There are three types of focus groups and/or semi-structured interviews commonly used to inform PRO instrument selection or development: exploratory, developmental, and confirmatory [7]. *Exploratory* focus groups or semi-structured interviews are conducted before instrument selection or development to provide insight into the patient experience of a disease in order to better understand a PRO concept(s). Data collected at this stage can be used to determine the relevance of concepts to patients. Building on this, *developmental* focus groups are designed to explicitly capture patient descriptions of the proposed concept of measurement, including the themes, topics, and language that patients use in describing their experience. Careful consideration at this point should be given to the questionnaire intent and purpose [35]. For example, if a measure is intended to assess symptom bother, interview questions should be designed to elicit the words and phrases patients use to describe the impact of their condition. Rather than using clinical terminology that patients may not understand, the words used during the focus groups or interviews should be common to patients. Moderator prompting should be designed to elicit emergent information rather than leading participants to prespecified responses. Finally, evaluative or *confirmatory* focus groups or interviews can be conducted to provide documentation that an existing instrument is appropriate for a given purpose and patient population. Qualitative data obtained in confirmatory focus groups can be used to map content, words, phrases, and themes to items from existing and/or newly developed instruments.

Saturation is defined as the point at which no substantially new themes, descriptions of concepts, or terms are introduced as additional focus groups or interviews are conducted [40]. The exact number of focus groups or interviews needed to reach saturation is determined by the number of concepts elicited, the complexity of these concepts, and the attributes of the patient population (e.g., age, severity). Although larger sample sizes (i.e., additional focus groups/interviews) may provide additional confirmation of the findings, it is important to recognize that there is a point at which additional qualitative research fails to provide new information—this is the point of saturation [7]. Saturation of concepts can be documented through a saturation grid (see Table 12.1).

After questionnaire items have been generated, the newly drafted questionnaire should be reviewed by other patients and experts to ensure its *readability* and provide additional evidence of *content validity*. Cognitive interviews are one-on-one interviews designed to uncover problems in the social-cognitive processes involved in completing a questionnaire [41]. The ISPOR task force [36] has outlined five good practices related to the use of cognitive interviews: (1) develop items based on findings from concept elicitation, (2) design cognitive interview process for the planned context of use, (3) conduct cognitive interviews, (4) make decisions to revise the PRO instrument (includes assessment of saturation), and (5) document cognitive interview results for evaluation of content validity (includes development of complete item-tracking matrix) (Figure 12.1).

During cognitive interviews, patients are typically asked to review and respond to the questionnaire items and are then interviewed about what each item meant to them as they completed the questionnaire. The results are used to make modifications in the words or phrases in the items, response options, recall period, and instructions or format of the instrument in order to improve ease of administration and enhance the validity [7]. This process is also important when reviewing or adapting an existing measure to meet the needs of a new patient population. The adapted questionnaire must be validated on its own in the target population; the validity of the original questionnaire does not apply to an adapted measure. Saturation should be demonstrated in the cognitive interviewing process in a similar way to that used in the initial focus group or one-on-one interview process used to generate items. Also valuable for content validity review is a listing of all changes made to each item in the instrument development process, the rationale for decisions to drop or change items, and a record of items added or dropped [2]. The development of the final PRO can be illustrated in an item-tracking matrix, which includes the final item, final response scale, any preliminary domain assignment, description of intent of item, and patient quotes supporting item intent [36].

Determining the Mode of Administration of a Questionnaire

Once items have been generated, the mode of administration must be considered. Will the measure be completed by the patient (i.e., self-administered) or administered by an interviewer (i.e., interviewer administered)? How the questionnaire will be completed needs to be determined before the validation stage because the mode of administration can affect patient responses. For highly personal or intimate questions or questions regarding satisfaction, a self-administered questionnaire is recommended to avoid response bias. Questionnaires that are self-administered are preferable to interviewer-administered questionnaires because the data collection burden is reduced and patients are more likely to provide unbiased information on self-administered questionnaires. Importantly, if a questionnaire has been validated for a particular mode of administration, this does not make the questionnaire valid for all modes of administration. Each mode of administration should be validated separately. This applies to varying modes of self-administration such as going from pen and paper to electronic; the new mode of administration needs to be demonstrated as equivalent to the initial mode of administration.

PRO PSYCHOMETRIC PROPERTIES

All PRO measures must demonstrate *reliability*, *validity*, and *responsiveness*, which are described in detail in the following text. This can be accomplished in several ways:

1. Perform a stand-alone cross-sectional study to validate the questionnaire in the patient population for which it was designed.
2. Administer the untested questionnaire in a clinical trial and use the baseline data to perform psychometric validation (the end-of-study data can also be used to evaluate responsiveness).
3. Perform a stand-alone longitudinal study with an intervention to determine the instrument’s psychometric performance and responsiveness in a nonclinical trial setting.

The following psychometric properties must be tested for and demonstrated in a validated questionnaire:

Reliability refers to the ability of a measure to produce similar results when assessments are repeated (i.e., is the measure reproducible?) [42–44]. Reliability is critical to ensure that change detected by the measure is due to the treatment or intervention and not due to measurement error [43].

Test–retest reliability, or reproducibility, indicates how well the results can be reproduced with repeated testing. To assess test–retest reliability, the same patient completes the questionnaire more than once, at baseline and again after a period of time during which the impact of symptoms is unlikely to change (e.g., a few days or weeks) [43]. The Spearman’s correlation coefficient and intraclass correlation coefficient are used to demonstrate reproducibility. For group data, a Spearman’s correlation coefficient or an intraclass correlation coefficient of at least 0.70 demonstrate good test–retest reliability [43].

Internal consistency reliability is another measure of reliability that indicates how well individual items within the same domain (or subscale) correlate [42,45]. Cronbach’s alpha coefficient is used to assess internal consistency reliability, with higher alphas indicating greater correlation [46,47]. Typically, Cronbach’s alpha should be greater than 0.70 to indicate good internal consistency reliability [3,43].

Interrater reliability indicates how well scores correlate when a measure is administered by different interviewers or when multiple observers rate the same phenomenon [42]. Demonstration of interrater reliability is not necessary for self-administered questionnaires but is necessary for instruments based on observer ratings or using multiple interviewers. A correlation of 0.80 or higher between raters indicates good interrater reliability [48].

Validity refers to the ability of an instrument to measure what it was intended to measure [3,42,43]. A measure should be validated for each specific condition or outcome for which it will be used. For example, a measure designed to assess stress incontinence would not be valid for OAB unless it was specifically validated in patients with OAB symptoms.

Evidence of content validity, convergent validity, discriminant validity, and criterion validity typically are required to validate a questionnaire [42]. As described previously in relation to qualitative research, content validity is a qualitative assessment of whether the questionnaire captures the range of the concept it is intended to measure. Construct-related validity refers to evidence that an instrument behaves in a way that is consistent with the theoretical implications associated with the constructs being measured [3].

Convergent validity is demonstrated by the extent to which the measure correlates with other measures designed to assess similar constructs [49]. *Discriminant validity* refers to the degree to which the scale does not correlate with other measures designed to assess dissimilar constructs or is able to discriminate between constructs that should be related [49]. Stronger relationships should be seen with the most closely related constructs and weaker relationships seen with less-related constructs [43]. Another common method for examining construct-related validity is to evaluate whether a questionnaire can differentiate between known patient groups (e.g., those with mild, moderate, or severe disease) [3]; generally, measures that are highly discriminative are also highly responsive [50].

Criterion validity reflects the correlation between the new questionnaire and an accepted reference or gold standard [3,51]. One difficulty in establishing criterion validity is that a gold-standard measure might not be available [3]. When criterion validity can be established with an existing measure, the correlation should be 0.40–0.70; correlations approaching 1.0 indicate that the new questionnaire may be too similar to the gold-standard measure and therefore redundant [3].

Responsiveness indicates whether the measure can detect change in a patient’s condition [3,43]. An important aspect of responsiveness is determining not only whether the measure detects change but whether the change is meaningful to the patient. This can be done by determining the *minimal important difference* (MID) of the measure. The MID is the smallest change in a PRO questionnaire score that would be considered meaningful or important to a patient [52,53]. A treatment that is statistically significantly better than another may not necessarily have a meaningful difference to the patient; the MID indicates whether the treatment made such a difference from a patient perspective [52,53].

Unfortunately, there is no scientific test for MID as it is an iterative process that typically involves two methodologies: an anchor-based approach and a distribution-based approach [54,55]. With the anchor-based approach, the MID is determined by comparing the measure to other measures (or “anchors”) that have clinical relevance, such as a global measure of well-being or perception of treatment benefit [52]. With the distribution-based approach, the MID is determined by the statistical distributions of the data, using analyses such as effect size, one-half standard deviation, and standard error of measurement [54,55].

LINGUISTIC AND CULTURAL VALIDATION

Increasingly, PRO questionnaires are required to be used in a number of different populations and settings; however, questionnaires and their psychometric properties are not necessarily transferable [56,57]. A measure that is valid and reliable for a particular language and culture may not prove so when used in a different population. Linguistic and cultural adaptation of a questionnaire occur during the development phase before validation, or it can be done after the questionnaire is validated in the language in which it was initially developed, with the latter being the more common approach. Ensuring the linguistic and cultural validity of a questionnaire is especially important for measures used in multinational clinical trials.

The principal steps in adapting a measure for different languages and cultures are as follows:

1. Two forward translations of the original instrument into the new language
2. Quality-control procedures that may include a backward translation (translating the instrument back into the original language) [58]
3. Adjudication of all translated versions
4. Discussion by an expert panel to ensure clarity of the translated questionnaire
5. Testing the translated instrument in monolingual or bilingual patients to ensure that it measures the same concepts as the original instrument [45,56,58]

However, if a backward translation of the measure does not produce a semantically equivalent instrument, then the instrument may need to be developed in the target language, rather than just translated [58].

After cultural and linguistic validation, PROs should also be psychometrically validated within the target language. Thus, reliability, validity, and responsiveness need to be assessed with each language translation to confirm the same measurement properties are present in the translated language(s) to ensure psychometric equivalence. If psychometric equivalence is not present (e.g., not achieving similar or better results in new language translation), the cultural and linguistic translations need to be reevaluated and perhaps revisions made to the existing instrument or a new instrument may need to be developed.

Regulatory Oversight

As clinicians and scientists have begun to appreciate and accept PROs as appropriate outcome measures, regulatory authorities have issued guidance documents on current best practices in the development and implementation of PRO in clinical trial settings [1,59]. Both the FDA and the European Agency for the Evaluation of Medicinal Products (EMEA) have released documents acknowledging the importance of PROs in clinical trials and providing recommendations about their use [1,37]. For PROs to be acceptable outcome measures for regulatory authorities, documentation of measurement properties must be present as well as qualitative evidence of inclusion of the patient perspective and understanding of the PRO. Importantly, a cohesive conceptual framework that stipulates how the PRO is related to the specific intervention must also be developed and presented to the regulatory authorities. It is strongly suggested that regulatory authorities be contacted early in the process of selecting a PRO for clinical trials to ensure regulatory acceptance of the PRO measure.

Questionnaire Modification

Most PROs have been developed for use with members of the general population or urology/gynecology patients with the specific condition (e.g., incontinence, OAB, POP). However, specific patient groups may experience particular problems or have unique needs that need to be addressed within the PRO (for example, children, frail elderly, spinal cord injuries, or those who are severely disabled). As such, a new questionnaire or modifications to an existing questionnaire may be needed that would require additional investigation and to establish relevance and content validity among the specific patient group. This situation also occurs when using a PRO to assess an outcome within a new patient population for which the PRO was not developed. Coyne et al. [60] evaluated several sexual health outcome measures to establish content validity of the PROs among women with OAB [61]. Since none of the PRO had been developed among women with OAB, this qualitative step was essential to evaluate relevance of the sexual health measures among this patient group.

Importantly, any modifications of established questionnaires may result in changes (sometimes substantial) in the psychometric performance of the instrument. Consequently, all modified instruments should be qualitatively reviewed first by the target patient population to ensure patient understanding and relevance as well as be subjected to the same psychometric testing as that employed in developing a completely new instrument. Specifically, modified instruments should report information regarding the instrument’s content validity, construct validity, reliability, and test–retest reliability, at a minimum, and sensitivity to change, in intervention studies.

SELECTING PRO MEASURES FOR CLINICAL TRIALS AND CLINICAL PRACTICE

The previous sections have provided an overview of PRO measure development and validation. But how does a researcher choose which instruments are most appropriate for a particular research study and/or clinical assessment? As there are many available PROs, it is of utmost importance to select the PRO measure that is relevant and applicable to one’s desired outcome. The goal is to develop a conceptually adequate yet practical PRO battery given the study population, the specific intervention, and the study design. If an intervention is designed to reduce symptom bother, then a relevant PRO would be a symptom bother measure. Multiple PROs can be included in a research study; however, the designation of the PRO as a primary or secondary endpoint must be *a priori*. In addition, issues of staff and participant burden, time constraints, and resources should be considered in the selection of a PRO measure.

Study Design Considerations

There are several protocol concerns that must be taken into account when implementing PRO measures in research studies, including the length of the study, the frequency of contact with the study participants, the timing of clinical assessments, the complexity of the trial design, the number of participants enrolled, and the participant and staff burden. The goal of the PRO investigation is to “fit” the PRO measures to the protocol without compromising either the study objective or the design. For example, if the study design is complex with frequent participant contacts and multiple clinical measures, it may be necessary to keep the PRO measures at a minimum or to reduce the number of times the PRO is assessed (e.g., baseline and end of study rather than during all participant contacts) to minimize participant and staff burden. At the same time, however, PROs must be viewed as an important variable in the overall trial design and cannot be devalued in the data collection process. Consequently, PRO measures cannot be altered or reduced to accommodate study design as such alterations may yield potentially less reliable measures or may seriously diminish the integrity of the overall study design and yield useless information. The frequency with which PRO will need to be assessed in a research study will depend upon the nature of the condition or intervention being investigated and the expected effects (both positive and negative) of treatment. At a minimum, as with all measurements collected in a research study, a baseline and end of study assessment should be completed. In addition, other PRO assessments should be timed to match expected changes in functioning due to the intervention, the condition, or the disease itself.

It is critical to specify the key population demographics that could influence the choice of instruments, the relevant dimensions of PRO to be assessed, and the mode of administration. Thus, age, gender, educational level, the language(s) spoken, and cultural diversity should be carefully considered prior to selecting PRO measures. For example, a cohort of patients over the age of 70 may have more vision problems than the middle-aged persons, making self-administered questionnaires potentially difficult. Ethnically, diverse groups also require measures that have been validated across different cultures and/or languages.

CONCLUSION

PROs provide vital information regarding disease impact and treatment outcomes from the patient’s perspective that is critical for urogynecologists. The development of a PRO questionnaire is an iterative, time-consuming process that involves many steps. As such, developing a new questionnaire is not a task that should be undertaken lightly. Prior to questionnaire development, ensure that a need for a new questionnaire exists and that existing PRO measures do not meet current needs or cannot be modified to meet current needs. If a new scale needs to be developed, ensure that the guidelines proposed by the FDA and EMEA on developing PROs are followed and that the appropriate expertise in questionnaire development and psychometrics is available to your research team in order to guide the questionnaire development process.

Patient-Reported Outcome Questionnaires to Assess Health-Related Quality of Life and Symptom Impact

Cornelius J. Kelleher, Ramandeep Basra, and Alexandra E. Ridout

Over the last decade, there has been tremendous growth in the number and breadth of patient-reported outcome (PRO) measures available for use in clinical practice and research, allowing assessment of a broad range of concepts. A PRO is “any report of the status of a patient’s health condition that comes directly from the patient, without interpretation of the patient’s response by a clinician or anyone else” [1].

It would be unusual for any clinical study of patients with lower urinary tract symptoms (LUTS) to not include at least one PRO questionnaire.

This chapter will cover three types of PRO, namely health-related quality of life (HRQL), symptom bother, and urgency specific measures. (Screener satisfaction and goal assessment tools are described in Chapter 14. PROs to evaluate bowel and sexual dysfunction are described in Chapters 15 and 16.) There is inevitable overlap between this chapter and that regarding the International Consultation on Incontinence (ICI) modular questionnaire in Chapter 17, however, where possible repetition has been avoided.

The *design, validation, and use* of PROs have been described in detail by Coyne and Sexton in Chapter 12 and therefore will not be repeated here.

All of the questionnaires included in this chapter are largely Grade A or B as outlined in the recently published Fifth International Consultation on Incontinence. Recently, the addition of a+ sign has been added to indicate when published content validity is available for an instrument. For the sake of clarity, the grading of questionnaires adopted from the ICI fifth consultation is outlined in the following texts. Where possible it is advisable to use questionnaires of the highest possible grade, providing they meet the requirements of the study or evaluation being undertaken.

- Questionnaires were “highly recommended” and given a *Grade A* if the ICI committee found “published data indicating that the questionnaire is valid, reliable, and responsive to change following standard psychometric testing.” Evidence must be published on all three aspects, and questionnaires must be relevant for use with persons with incontinence. *Grade A+ indicates there is additional evidence of published content validity*.
- Questionnaires were “recommended” and given a *Grade B* if the committee found “published data indicating that the questionnaire is valid and reliable following standard psychometric testing.” Evidence must be published on two of the three main aspects (usually validity and reliability). *Grade B+ indicates there is additional evidence of published content validity*.
- Questionnaires were considered to have “potential” and given *Grade C* if the committee found “published data (including abstracts) indicating that the questionnaire is valid or reliable or responsive to change following standard psychometric testing.” *Grade C+ indicates there is additional evidence of published content validity*.

As there are so many PROs, it is of utmost importance to select the measure that is relevant and applicable to one’s desired outcome. If an intervention is designed to reduce symptom bother, then a relevant PRO would be a symptom bother measure. Multiple PROs can be included in clinical practice or in a research study; however, the designation of the PRO as a primary, coprimary, secondary, tertiary, or exploratory endpoint must be noted. In addition, issues of staff and participant burden, time constraints, and resources should be considered in the selection of a PRO measure. Once it has been decided which outcomes are to be assessed, it is important to choose a questionnaire that has been scientifically developed and validated.

As a general rule, most studies will use a HRQL measure and additional symptom specific scales. Care must be exercised to avoid questionnaire overload, and only questionnaires that are deemed useful should be chosen.

But how does a researcher choose which instruments are most appropriate for a particular research study and/or clinical assessment? Clearly, there are many questionnaires to choose from, and determining the most fitting option requires some guidance. The goal of the PRO assessment is to “fit” the PRO measures to the protocol without compromising either the study objective or the design. Having well-developed research goals and questions regarding PROs will help to guide you in the selection of measures for a study. The aim is to develop a conceptually adequate, yet practical PRO battery given the study population and design and the specific intervention.

1. *Try to select a Grade A/Grade A+ questionnaire if available.*
2. *Understand the questionnaire content.*

   There is no replacement for reading and understanding the content of the questionnaire, the layout of the questionnaire, the scoring system, the presentation, and how the questionnaire is completed.
3. *What is the target population?*

   It is critical to specify key population demographics that could influence the choice of instruments, the relevant dimensions of the PRO to be assessed, and the mode of administration.

   What is the intended age range, and are the respondents men, women, or both? Are the target population patients with specific LUT problems or patients with mixed diagnoses?
4. *Where is the study to be carried out?*

   Is there a need for linguistically validated versions of the questionnaire, of particular importance for multinational studies, or inner city studies with mixed cultural populations?
5. *How often will the questionnaire be completed?*

   Is there any benefit in using a complex and longer questionnaire when a short-form (SF) questionnaire would offer adequate information? This is particularly important in busy clinical settings or when patients are expected to complete many other questionnaires at the same time.
6. *Has the questionnaire previously been used successfully?*

   If possible, use questionnaires that have a proven track record in the area that you intent to study. If many studies of stress incontinent (SI) patients or patients with overactive bladder (OAB) have utilized a questionnaire, did it respond as expected and was the choice of questionnaire good?
7. *Are there specific issues that you need to investigate?*

   If you need to investigate certain issues, make sure the questionnaire you choose has appropriate questions and covers the problem in sufficient depth. If, for example, a study of nocturia is performed, does the questionnaire suitably cover aspects of sleep deprivation, tiredness, work impact, etc.?
8. *Is the questionnaire recognized by the audience, governmental, or regulatory body that will review and credit the results?*

   This may seem obvious but is extremely important. Check before starting clinical trials and studies that the outcomes used will be accepted if necessary by the appropriate regulatory agencies. Stringent criteria for design and validation of questionnaires are usually required, and it is normally desirable that validation data are available in a country-specific fashion. Is the questionnaire recognized and widely used in the country where the study is to be conducted? Will the audience recognize and understand the questionnaire and results when you present your study?

HEALTH-RELATED QUALITY OF LIFE MEASURES

HRQL measures help to assess the impact of disease and treatment on those aspects of quality of life related to health. The term “quality of life” is linked to the WHO definition of health that refers to a state of physical, emotional, and social well-being and not just the absence of disease or infirmity [2].

HRQL PROs are multi-item questionnaires that usually collect information on various aspects or “domains” relating to a patient’s life. These domains may relate to sleep, energy, emotions, social life, work life, sexual problems, etc., but vary to some extent between the different questionnaires. The results are usually presented as impairment in individual domains (e.g., physical or emotional function) and for intervention studies improvement in the respective domains after treatment. It is possible for some of the questionnaires to provide a summary score "overall HRQL" but this means that the value of measuring the individual domains is lost in the overall presentation of results. Such questionnaires are useful in health economic studies where a summary score is desirable.

There are two major types of HRQL PRO: generic and condition specific. These are discussed by Coyne in Chapter 12.

Generic questionnaires are designed to assess all patients with all conditions and are also used as population survey tools. They allow comparison of different groups of patients and different illnesses. Generic measures are designed to assess outcomes in a broad range of populations (e.g., both health and ill individuals). These instruments are generally multidimensional and assess at least the physical, social, and emotional dimensions of life. They are often, however, insufficiently sensitive to measure clinically relevant change when applied to patients with lower urinary tract dysfunction. For the purpose of this chapter, only condition-specific HRQL questionnaires are discussed (i.e., in this context questionnaires designed for the assessment of HRQL among patients with LUTS).

The condition-specific measures can be similar to generic instruments in that they assess multiple outcome dimensions but are also designed to include items more specific to the particular condition or population being studied. Examples of condition-specific instruments in the study of lower urinary tract dysfunction include the Incontinence Impact Questionnaire (IIQ) [3], the King's Health Questionnaire (KHQ), [4] and the Overactive Bladder Questionnaire (OAB-q) [5].

In general, the growing trend has been to include condition-specific outcome measures in clinical trials due to their enhanced sensitivity to change and the need to minimize participant burden. Importantly, the type of instruments selected for inclusion in a research study will depend on the goals of the intervention and the specific research questions to be addressed.

As HRQL questionnaires cover many different domains, they tend to be longer and consequently require greater time for completion than single item or summary measures. When time constraints exist and/or questionnaires are to be completed on many different occasions, or multiple questionnaires are to be used, this may be an important consideration. Overall, the value of such questionnaires far outweighs these considerations. Some of the questionnaires do have a SF version, which allows them to overcome this potential problem. It is important to look at the SF version in detail to ensure that you are able to collect the information you require and do not sacrifice clarity for the sake of brevity.

Coyne and Sexton discuss the issue of questionnaire responsiveness in their chapter with reference to minimal important difference (MID). This refers to the smallest change in PRO score that would be deemed clinically meaningful to a patient. MID values have been calculated for both the KHQ and the OAB-q and are commonly used in data analysis and presentation of PRO results [6].

One drawback of multidomain questionnaires is their inability to probe with great detail into any specific problem. This issue is discussed by Domoney and Symonds in their chapter on sexual dysfunction. Greater detail requires a greater number of questions, which would make HRQL questionnaires excessively lengthy and cumbersome. It is for this reason that studies will often employ a HRQL questionnaire in addition to specific questionnaires to measure in greater depth problems such as sexual dysfunction, sleep disorder, and depression when these issues are selective important outcomes to measure.

Increasingly, HRQL outcomes measures are being used in the development of quality-adjusted life-year (QALY) measures. A QALY is a universal health outcome measure applicable to all individuals and all diseases, which combines gains or losses in both life quantity (mortality) and life quality (morbidity) and enables comparisons across diseases and programs (reference development of QALY from KHQ [7]). This topic is addressed in detail by Kate Moore in her chapter on health economics.

In Table 13.1, the major condition-specific HRQL questionnaires for the assessment of patients with lower urinary tract dysfunction are listed in alphabetical order. Their purpose, psychometric properties, translation availability, and recommended ICI grade are also listed. Some of the more commonly used Grade A questionnaires are listed later.

BFLUTS and BFLUTS-Short Form

The long form of the Bristol Female Lower Urinary Tract Symptoms (BFLUTS) [8,9] was developed for use with women, following the pattern established for the questionnaire developed for the international continence society benign prostatic hyperplasia (ICS-"BPH") study. The questionnaire covers the occurrence and bothersomeness of symptoms relating to incontinence and other LUTS. It has shown good levels of validity and reliability and has been increasingly used in epidemiological and outcome studies [10–13]. Validity, reliability, and responsiveness have been demonstrated, and a scored SF has been produced, which is now the recommended version [14,15].

Danish Prostatic Symptom Score

This questionnaire was designed in Denmark to measure the degree to which men are bothered by urinary symptoms [16,17]. A composite score is achieved by the multiplication of the "symptom" by the "bother" score, with a total range of 0–108. A computer version of this questionnaire has been validated and patients seemed to appreciate more of this new version than the paper version [18]. It is primarily a questionnaire for the assessment of the occurrence and bothersomeness of a wide range of LUTS in men including symptom assessment after stroke [19], in patients with Parkinson's disease [20], and in the assessment of sexual dysfunction associated with BPH [21]. There are 10 linguistic versions of the scale [22].

International Continence Society *Male* and ICS *Male* SF

The ICS *Male* questionnaire contains 22 questions on 20 urinary symptoms and, for most questions, the degree of problem that the symptom causes [9]. It has exhibited acceptable levels of validity, reliability, and sensitivity to change following a range of treatments including surgery, minimally invasive therapies, and drug treatments [9,23,24]. This long version has been largely replaced now by a scored SF—ICS *male* SF [25]. It is primarily a questionnaire for the assessment of the occurrence and bothersomeness of a wide range of LUTS in men.

IIQ and IIQ-7

This questionnaire was developed to assess the psychosocial impact of urinary incontinence in women and consists of 30 items (24 on the degree to which incontinence affects activities and six on the feelings engendered) [3,26,27]. Scores are obtained overall or for four subscales determined by factor and cluster analyses: physical activity, travel, social relationships, and emotional health. The IIQ has been found to have acceptable levels of reliability and validity across a range of studies [28,29] and has been recommended for use by the National Institute for Health and Care Excellence (NICE) [15]. The IIQ has also been produced in an SF comprising seven items, also with evidence of validity and reliability [30]. Responsiveness of the IIQ has been assessed in several intervention studies [31].

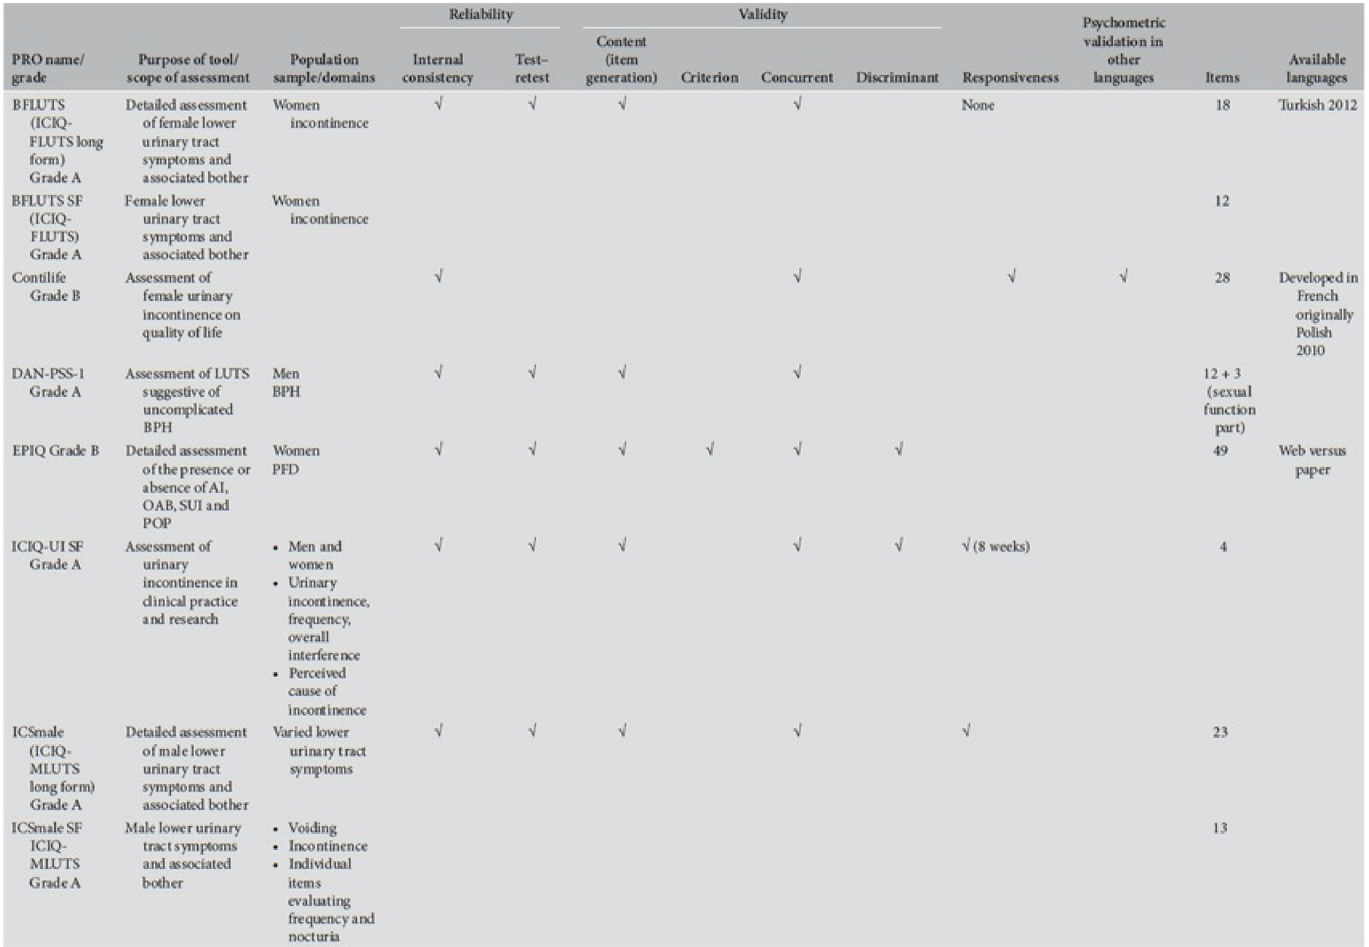
International Quality of Life

This questionnaire was designed to be used in clinical trials to measure the impact of incontinence on men and women [32]. Psychometric information on translated versions of the International Quality of Life (I-QOL) have been reported for French, Spanish, Swedish, German, Korean, and Thai language versions [33–35]. Other cultural and linguistic adaptations are available but have not been validated. In all countries, the use of three subscales, and an overall summary score was confirmed to be useful. The I-QOL has been recommended for use by NICE in the assessment of LUTS and quality of life impact [15].

KHQ

The KHQ consists of three parts [4]. The first section contains two questions measuring general health and overall health related to urinary symptoms. The second section includes 19 questions divided into seven domains of quality of life: incontinence impact, role limitations, physical limitations, social limitations, personal relationships, emotions, sleep and energy, severity coping measures, general health perception, and symptom severity. The third section of the questionnaire comprises 11 questions measuring the bother or impact of urinary symptoms. The KHQ has demonstrated reliability and validity in men and women and is available in 39 languages [36–39].

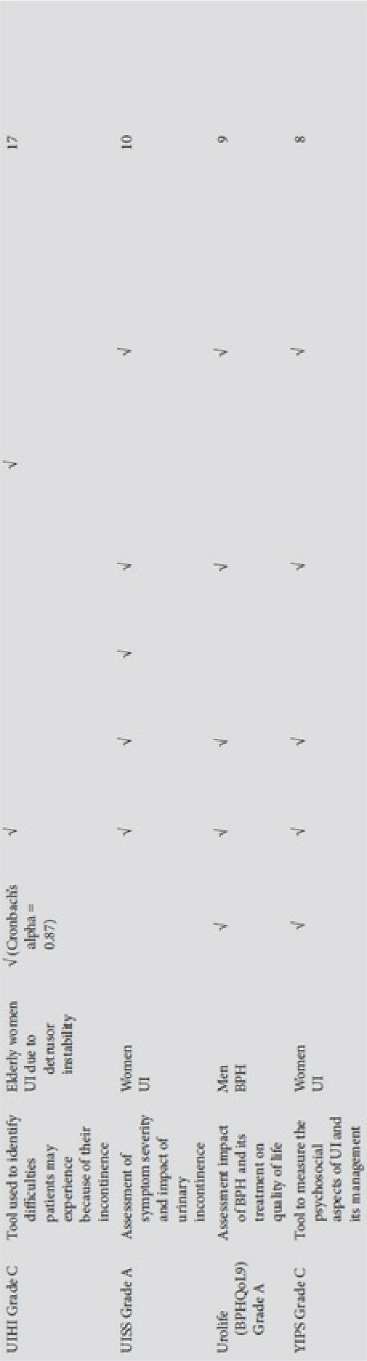
Table 13.1 Summary of Patient-Reported Outcome Measures in Patients with Urinary Incontinence, Overactive Bladder, and Lower Urinary Tract Symptoms: Health-Related Quality of Life



PRO name/ grade	Purpose of tool/ scope of assessment	Population sample/domains	Reliability		Validity				Responsiveness	Psychometric validation in other languages	Items	Available languages
			Internal consistency	Test-retest	Content (item generation)	Criterion	Concurrent	Discriminant				
BFLUTS (ICIQ-FLUTS long form) Grade A	Detailed assessment of female lower urinary tract symptoms and associated bother	Women incontinence	√	√	√		√		None		18	Turkish 2012
BFLUTS SF (ICIQ-FLUTS) Grade A	Female lower urinary tract symptoms and associated bother	Women incontinence									12	
Contilife Grade B	Assessment of female urinary incontinence on quality of life		√				√		√	√	28	Developed in French originally Polish 2010
DAN-PSS-1 Grade A	Assessment of LUTS suggestive of uncomplicated BPH	Men BPH	√	√	√		√				12 + 3 (sexual function part)	
EPIQ Grade B	Detailed assessment of the presence or absence of AI, OAB, SUI and POP	Women PFD	√	√	√	√	√	√			49	Web versus paper
ICIQ-UI SF Grade A	Assessment of urinary incontinence in clinical practice and research	• Men and women • Urinary incontinence, frequency, overall interference • Perceived cause of incontinence	√	√	√		√	√	√ (8 weeks)		4	
ICSmale (ICIQ-MLUTS long form) Grade A	Detailed assessment of male lower urinary tract symptoms and associated bother	Varied lower urinary tract symptoms	√	√	√		√		√		23	
ICSmale SF ICIQ-MLUTS Grade A	Male lower urinary tract symptoms and associated bother	• Voiding • Incontinence • Individual items evaluating frequency and nocturia									13	

ICSQoL Grade A	Assess impact of LUTS on patients' lives	Men LUTS Possible BPH	√	√	√		√			√	8	
IIQ Grade A	Assessment of severity of UI on HRQL	Women UI SUI		√	√		√		√ (12 weeks)	√	30	
IIQ-7 (SF) Grade A	Assess impact of UI on HRQL	Men after radical prostatectomy who had UI	√	√	√	√	√	√		√	7	
IOQ Grade B	Assessment of female quality of life after surgery for stress urinary incontinence	Women SUI	√		√	√			√	√	27	
I-QOL (ICIQ-Uiqol) Grade A			√	√	√			√	√		22	20
ISI Grade C	Recommended by the WHO for studying the epidemiology of incontinence and other LUTS	Women				√	√				2	
ISQ Grade C	Assessment of psychological stress associated with urinary incontinence	Women	√	√							40 (20 sf)	
ISS Grade A	Self-assessment of severity of female urinary storage and voiding symptoms	Women		√			√		√ (duration not specified)		8	
KHQ (ICIQ-LUTSqol) Grade A+	HRQL issues associated with urinary symptoms and related bother	• Life restrictions • Emotional aspects • Preventive measures	√ (except severity measure)		√	√	√	√	√ (12 weeks)		21	39

LIS Grade A	Assessment of quality of life for males and females with urinary store symptoms of urgency, frequency, nocturia, and incontinence		√	√	√		√		√	21	
N-QoL (ICIQ-Nqol) Grade A+	Detailed assessment of HRQL issues associated with nocturia	• Issues associated with sleep disturbance • Life restrictions • Preventative measures • Men and women	√	√	√		√	√	√	13	
OAB-q (ICIQ-OABqol) Grade A	Detailed assessment of HRQL issues associated with overactive bladder	• Coping • Concern/ worry • Sleep • Social interaction • Continence and incontinence OAB	√	√ (ICC = 0.93 for 4-week recall period)	√	√	√		√ (12 weeks)	25	
OAB-q SF Grade A	Shortened version of OAB-q used to evaluate both continent and incontinent symptoms of OAB and their impact on HRQL	• OAB • Men and women	√	√	√		√	√	√ (12 weeks)	19	14
PRAFAB Grade A	Assessment used widely in the Netherlands to evaluated treatment effects for UI in women	Women UI	√	√	√		√	√	√	5	



UIHI Grade C	Tool used to identify difficulties patients may experience because of their incontinence	Elderly women UI due to detrusor instability	√ (Cronbach's alpha = 0.87)	√				√		17
UISS Grade A	Assessment of symptom severity and impact of urinary incontinence	Women UI		√	√	√	√		√	10
Urolife (BPHQoL9) Grade A	Assessment impact of BPH and its treatment on quality of life	Men BPH	√	√	√		√		√	9
YIPS Grade C	Tool to measure the psychosocial aspects of UI and its management	Women UI	√	√	√		√		√	8

Sensitivity to change has been shown successfully in clinical trials where it has been used to assess the HRQL improvement following treatment for patients with OAB, urodynamic stress incontinence (USI), and mixed incontinence symptoms [40–43]. Its use in the assessment of LUTS and quality of life impact is recommended by NICE [15]. A minimally important difference has been derived to establish clinically meaningful interpretations of the KHQ scores, and a QALY measure has been derived from KHQ scoring [6,7].

Leicester Impact Scale

The Leicester Impact Scale (LIS) is a condition-specific HRQL measure for men and women assessing the symptoms of urgency, frequency, nocturia, and incontinence. It is an interviewer-administered tool, so it is not a true PRO as interviewer administration can introduce potential bias into the patient responses. The LIS has utility in the clinical and research settings [44].

Overactive Bladder Symptom and Health-Related Quality of Life (OAB-q) and OAB-q SF

The OAB-q is a 33-item questionnaire developed to assess the symptom bother (8 items) and HRQL impact of OAB (25 items and 4 domains: coping, concern/worry, sleep, and social interaction) [45]. It has demonstrated reliability, validity, and responsiveness in multiple clinical studies of men and women [46]. A minimally important difference has been derived [47] to establish clinically meaningful interpretations of the OAB-q scores, and a QALY measure has been derived from OAB-q scoring [48]. The 19-item SF (OAB-q SF) is a 6-item symptom bother scale and 13-item HRQL scale that is a single score, which has also demonstrated reliability, validity, and responsiveness to change [49]. The OAB-q was the basis for the OAB-V8 awareness tool to screen for symptoms of OAB [5] and has been used in a Parkinson's disease patient population [50].

UDI and UDI-6

This questionnaire was developed in the United States with women to assess the degree to which symptoms associated with incontinence are troubling [3]. It contains 19 LUTS and has been shown to have high levels of validity, reliability, and responsiveness in community-dwelling women with incontinence and women over 60 years of age [51]. Responsiveness to changes in clinical status as or a result of treatment has been reported in a number of areas: comparing abdominal and vaginal prolapse surgery [52] and the use of a simple urethral occlusive device [53]. A SF version of the Urogenital Distress Inventory (UDI-6 SF) has been shown to be valid and reliable in older adult males and females [54,55], with demonstrated responsiveness to reconstructive pelvic surgery, tension-free vaginal tape [56], and imipramine [57].

ASSESSING SYMPTOM BOTHER AND OVERALL BOTHER

Bother questionnaires assess the impact or bother of symptoms rather than their presence or absence. Although superficially simplistic patients make many valued judgments to score these questionnaires and to patients they are a hugely important assessment of condition severity. These measures, particularly the patient perception of bladder condition (PPBC), are frequently used in clinical studies and clinical trials. They are short and relatively easy to complete and usually appear to be clinically meaningful. Measures that can be used to assess how bothered patients are by urinary symptoms are included in Table 13.2. The PPBC [63] and the UDI are the only Grade A recommended instruments. There are several Grade B and C measures, which assess bother for incontinence and LUTS.

Patient Perception of Bladder Condition Questionnaire

The PPBC is a single-item questionnaire designed to rapidly assess patients' perception of their bladder condition [63]. The questionnaire asks patients to choose one of six statements that best describes their present bladder condition. The scale was validated during two large 12-week clinical studies evaluating the efficacy and tolerability of tolterodine in patients with OAB. Patients taking part in the studies completed the PPBC, OAB-q, KHQ, and bladder diaries. Baseline and week 12 data were used for statistical analysis. PPBC scores were well correlated with OAB-q questionnaire scores and bladder diary variables. Correlations of the KHQ and PPBC were significant for all KHQ domains with the exception of the general health perception domain. The scale was found to be responsive to change in OAB symptoms and to have discriminant validity as reflected in the OAB-q, KHQ score, and bladder diary changes. The PPBC has also shown to have good test–retest reliability [63]. This scale has been widely used in studies evaluating the use of drug therapy in patients with OAB [64–66].

UDI-6

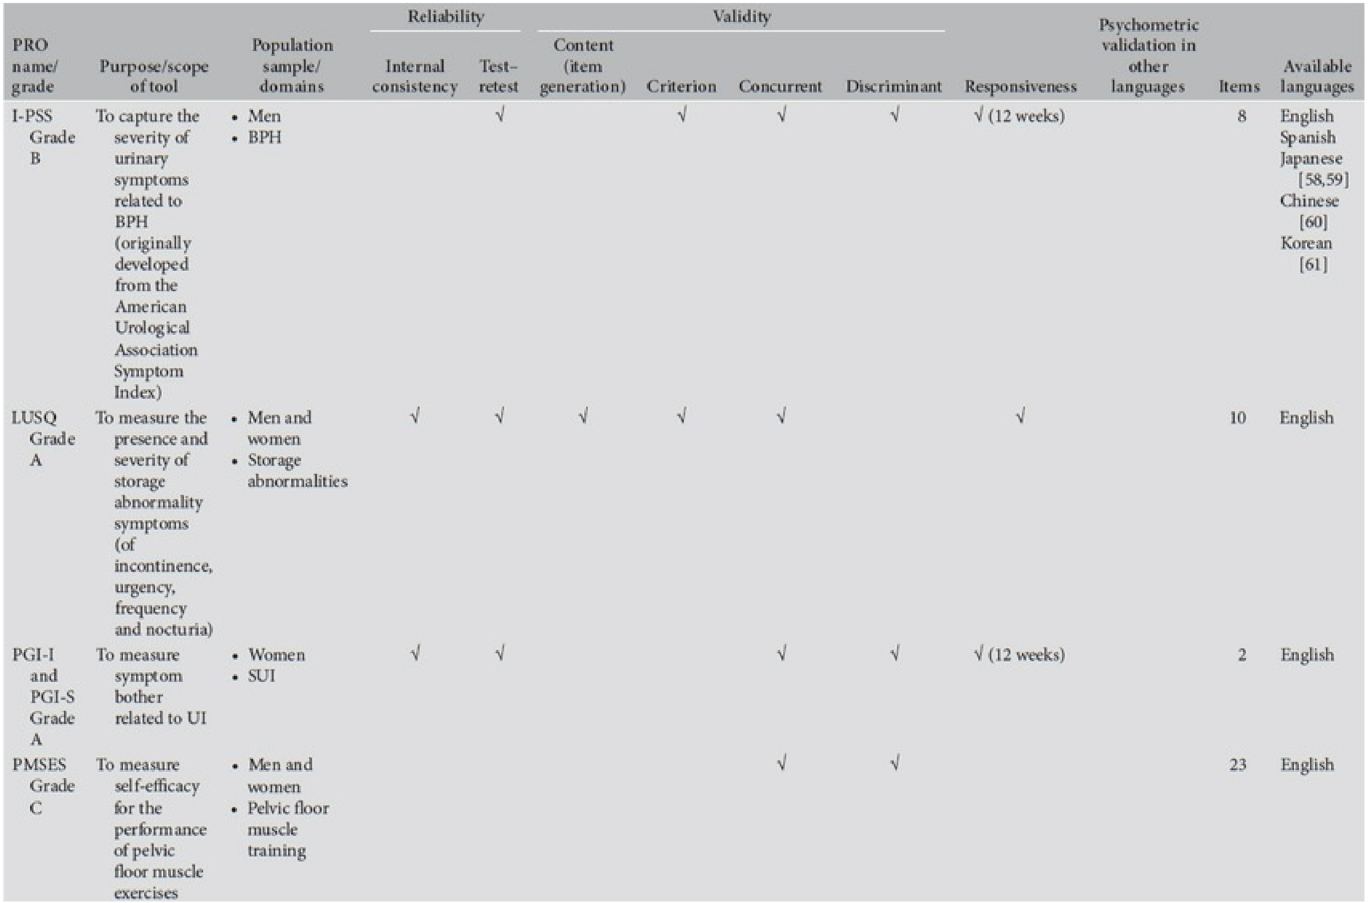
The UDI-6 is a six-item questionnaire that assesses the presence and bother of six LUTS [55]. The UDI-6 assesses the types of incontinence, frequency, difficulty emptying the bladder, and pain/discomfort in the lower abdomen/genitalia. The response options are zero to three. The instrument has demonstrated validity, reliability, and responsiveness [67].

Assessing the Impact of Urgency

Several instruments have been developed specifically to assess urinary urgency, which is defined by the

ICS as “the complaint of a sudden compelling desire to pass urine which is difficult to defer [68].” Urgency is the principal symptom of OAB, and, as such, assessing the effect of treatment on this symptom and its impact on HRQL is important. With any measure designed to evaluate urgency, patients must be able to distinguish between the normal desire to urinate (urge) and the difficulty to postpone the need to urinate (urgency) [69,70]. Wording thus becomes critical in the development of urgency assessment measures. Chapple and Wein [71] make a case for describing urgency as a “compelling desire to void in which patients fear leakage of urine” as a means of distinguishing this abnormal sensation from the normal need to void. However, some patients may have a sensation of urgency without fear of leakage, further complicating attempts to define urgency. Importantly, with some of these scales, patients have the option of indicating that they experienced urge urinary incontinence (UUI) (an event) rather than the strongest feeling of urgency (a sensation) itself. In such cases, patients who have severe urgency, but not UUI, do not have an option for endorsing the highest (worst) value because they are not incontinent. Urgency severity scales that include a UUI response option thus may be less useful than those that do not because such scales are trying to measure two things at once, both urgency and UUI.

Table 13.2 Summary of Patient-Reported Outcome Measures in Patients with Urinary Incontinence, Overactive Bladder, and Lower Urinary Tract Symptoms: Symptom Bother



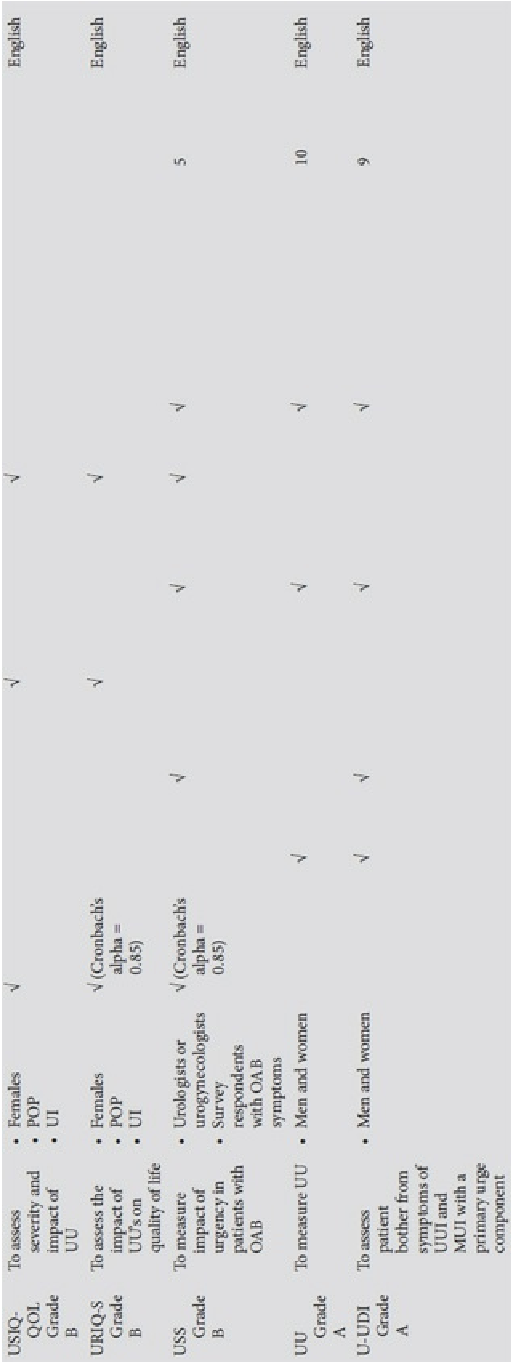
PRO name/ grade	Purpose/scope of tool	Population sample/ domains	Reliability		Validity					Psychometric validation in other languages	Items	Available languages
			Internal consistency	Test–retest	Content (item generation)	Criterion	Concurrent	Discriminant	Responsiveness			
I-PSS Grade B	To capture the severity of urinary symptoms related to BPH (originally developed from the American Urological Association Symptom Index)	• Men • BPH		√		√	√	√	√ (12 weeks)		8	English Spanish Japanese [58,59] Chinese [60] Korean [61]
LUSQ Grade A	To measure the presence and severity of storage abnormality symptoms (of incontinence, urgency, frequency and nocturia)	• Men and women • Storage abnormalities	√	√	√	√	√		√		10	English
PGI-I and PGI-S Grade A	To measure symptom bother related to UI	• Women • SUI	√	√			√	√	√ (12 weeks)		2	English
PMSES Grade C	To measure self-efficacy for the performance of pelvic floor muscle exercises	• Men and women • Pelvic floor muscle training					√	√			23	English

POSQ Grade C	To assess which symptom of OAB is the most bothersome to patients	• Men and women • OAB		√	√						5	English
PPBC Grade A	To assess patients' subjective impression of their current urinary problems (developed as a global assessment of bladder condition)	• Men and women		√			√		√	√	1	English
PFBQ Grade B	To assess symptoms of UI, UU and frequency, urge incontinence, FI, obstructed defecation, dyspareunia, and POP	• Women over the age of 18 • UI, UUI and SUI	√	√	√	√		√			9	English
SPI Grade B	To measure how troublesome patients find their urinary symptoms	• Men • BPH									7	English

SSI and SII Grade B	To measure SI severity/ impact or bothersome of symptoms	• Women undergoing SI surgery		√	√		√			√	3	English
UI-4 Grade C	To assess how bothered patients are by UI	• Women • UI					√				4	English
UDI Grade A	To assess symptom bother related to UI (complement to the IIQ)	• Women • UI and SUI	√	√	√		√	√		√	19	English Italian [62]
UDI-6 Grade A	To assess LUTS including incontinence	• Women	√	√	√	√	√	√	√	√	6	English Arabic

Table 13.3 Summary of Patient-Reported Outcome Measures in Patients with Urinary Incontinence, Overactive Bladder, and Lower Urinary Tract Symptoms: Urgency

PRO name / grade	Purpose/scope of tool	Population sample/domains	Reliability		Validity				Responsiveness (treatment duration)	Psychometric validation in other languages	Items	Available languages
			Internal consistency	Test-retest	Content (item generation)	Criterion	Concurrent	Discriminant				
IUSS Grade A	To quantify the level of urgency associated with void (as measured during standard voiding diaries)	Men and women • OAB with UI		√	(√)	√	√	√	√ (12 weeks)		1	English
PPIUS Grade B	To assess patient perception of urgency intensity	• Women • UUI		√					√		1	English
SUIQ Grade B	To differentiate between SUI and UUI	• Women • UI		√			√				2	English
U-IIQ Grade A	To assess the interference of urine leakage and bladder problems	• MUI • UUI • Developed for use in patients with all types of incontinence	√	√			√	√	√ (12 weeks)		32	English
UPS Grade B	To grade the urge to void and to assess the reason to void	• Men and women	√	√			√	√			5	English
UPS Grade B	To assess the severity of urgency	• Men and women • OAB			√		√	√	√		1	English
UQ Grade B	To assess severity and impact of urinary urgency symptoms on HRQL	• Women • OAB • Use of a VAS scale	√	√	√		√	√	√ (10 days)		15-Likert Scale Item and 4-VAS tool	English
URIS-24 Grade B	To assess UI in older persons	• Older persons • UI	√	√	√		√				24	English



USIQ-QOL Grade B	To assess severity and impact of UU	• Females • POP • UI	√			√		√			English
URIQ-S Grade B	To assess the impact of UU's on quality of life	• Females • POP • UI	√ (Cronbach's alpha = 0.85)			√		√			English
USS Grade B	To measure impact of urgency in patients with OAB	• Urologists or urogynecologists • Survey respondents with OAB symptoms	√ (Cronbach's alpha = 0.85)		√		√	√	√	5	English
UU Grade A	To measure UU	• Men and women		√			√		√	10	English
U-UDI Grade A	To assess patient bother from symptoms of UUI and MUI with a primary urge component	• Men and women		√	√		√		√	9	English

Several instruments have been developed to assess urinary urgency, and these are summarized in Table 13.3. A brief summary of each urgency measure is presented in the following texts.

The *urgency perception scale* was designed for use in clinical trials to evaluate patient-perceived urgency [72]. This instrument consists of a single question asking patients to describe their typical experience when they feel the need to urinate. The three possible responses are as follows: “I am usually not able to hold urine,” “I am usually able to hold urine until I reach the toilet if I go immediately,” and “I am usually able to finish what I am doing before going to the toilet” [72]. This scale was validated in a clinical trial evaluating the efficacy of tolterodine in treating OAB symptoms; however, its limited responsiveness may preclude its usefulness in clinical practice [73].

The *Indevus urgency severity scale* asks patients to rate their level of urgency on a four-point scale, from zero (no urgency) to four (extreme urgency discomfort that abruptly stops all activities/tasks) [74]. The scale has been validated in a clinical trial of trospium in patients with OAB [74], but Chapple et al. [73] question whether this scale actually measures urgency or just the normal urge to void.

The *urinary sensation scale* is a five-point scale ranging from one (no urgency; can continue activities until it is convenient to use the bathroom) to five (urge incontinence; extreme urgency discomfort, cannot hold urine, and have a wetting accident before arriving at the bathroom) [75]. The content validity of this scale was established through a physician survey and patient interviews [75].

The *urgency rating scale*, recommended by the European Medicines Evaluation Agency, consists of a five-point rating scale to be rated with every void, ranging from one (no urgency; I felt no need to empty my bladder but did so for other reasons) to five (urge incontinence; I leaked before arriving at the toilet). This scale was used in a tolterodine clinical trial, in which responses on this scale were used to calculate sum urgency, a measure that accounts for changes in both urgency and frequency [76,77].

CONCLUSION

A questionnaire design is a complex and lengthy process reinventing the wheel unnecessary for the vast majority of cases. A careful read of the chapter by Cotterill and Abrams will reveal that many of the questionnaires discussed in this and the chapter by Kopp have been adopted by the International Consultation as modules for the International Consultation on Incontinence Questionnaire.

There are clearly many different questionnaires and types of questionnaires from which to choose. Plan a study carefully with respect to what you expect to measure and which populations you intend to survey, and read the content of a questionnaire carefully. The value of spending time to make an informed and careful decision will, however, always be worth the effort.

Patient-Reported Outcome Questionnaires to Screen and Measure Satisfaction, Expectations, and Goal Achievement

Zoe S. Kopp and Christopher J. Evans

This chapter reviews PRO questionnaires that assist urogynecologists in patient screening, setting realistic patient expectations that lead to goal achievement and assessing satisfaction. Symptom and condition screeners help identify health conditions to identify patients who may benefit from treatment. Patient expectation, goal assessment, and satisfaction questionnaires help clinicians understand the patients' point of view regarding their treatment goals and expectations so that the clinician can enhance the probability of a satisfactory outcome. Other chapters in this section focus on PROs that assess function and health-related quality of life, the development of PROs, and their effective implementation in clinical trials.

As with other PROs, the development of screeners, expectation, goal assessment, and satisfaction questionnaires must done scientifically, following recommended development guidelines, and have been psychometrically validated to ensure that results are accurate [1–3].

The development process steps from conceptual design through cognitive debriefings, psychometric, and linguistic validation are described in detail earlier in this section. Whether using a PRO in clinical practice or research, it is important to verify the validity of multiple aspects of the tool including the way in which it was developed, administration (paper or electronically), the population in which it is to be used (elderly, surgical, etc.), and the usage setting (clinical practice versus research). When using PROs in multilingual environments, the tool should be linguistically validated instead of merely translated. This chapter introduces you to some useful, validated questionnaires for female urological practice.

SCREENING TOOLS

Patient-completed screeners can facilitate appropriate diagnosis and treatment in urogynecological clinical practice. Most clinicians recognize that many patients find it difficult to articulate their health issues for a variety of reasons such as embarrassment about their problem or lack of medical knowledge or language. Providing questionnaires that screen for common urogynecological conditions to patients before their medical consultation can help focus the medical visit. In this section, validated screeners, their individual strengths and weaknesses, and how to obtain them are presented.

Compared to the other PROs, screeners have additional criteria they must satisfy in order to be considered sound measurement tools. When choosing and interpreting the results of screeners, the sensitivity and specificity of the measures should be considered. Sensitivity is the probability of a positive screener score in a patient with the condition. That is, how likely is someone with the condition to score positive? At the same time, the screener should have a high likelihood of correctly identifying individuals without the condition—specificity. Screeners alone are not diagnostic; clinicians should verify the indicated condition before determining treatment.

LOWER URINARY TRACT SYMPTOMS SCREENERS

To improve the detection of incontinence, overactive bladder (OAB), and other lower urinary tract symptoms (LUTS), several screening questionnaires have been developed (Table 14.1). These tools help patients self-describe symptoms and facilitate diagnosis of LUTS by the clinician. Only the Bladder Self-Assessment Questionnaire (B-SAQ) has been designed to screen for general LUTS rather than solely symptoms of one condition. The majority of patients with LUTS have mixed urinary symptoms, and therefore a questionnaire, which can detect more than one symptom complex, may be more functional as a screening tool in clinical practice than a highly specific questionnaire. There are several condition-specific screeners available, which assess common female urological problems such as OAB, stress urinary incontinence (SUI), and interstitial cystitis (IC). The OAB-V8/V3, Overactive

Bladder Symptom Score, and Questionnaire for Urinary Incontinence Diagnosis are all validated, short, simple to understand, complete, and easy to interpret, which screen for OAB. Importantly, with screeners, responsiveness is not assessed; however, the sensitivity and specificity of each tool is critical. The International Consultation on Incontinence has evaluated many LUTS questionnaires, and you can obtain information about their recommended questionnaires at www.iciq.net [4].

In this section, we describe some commonly used screeners and factors such as which populations the screener can be used in, its reliability and validity, its sensitivity and specificity, and its availability of valid linguistic translation. Details about these screeners and others are included in Table 14.1.

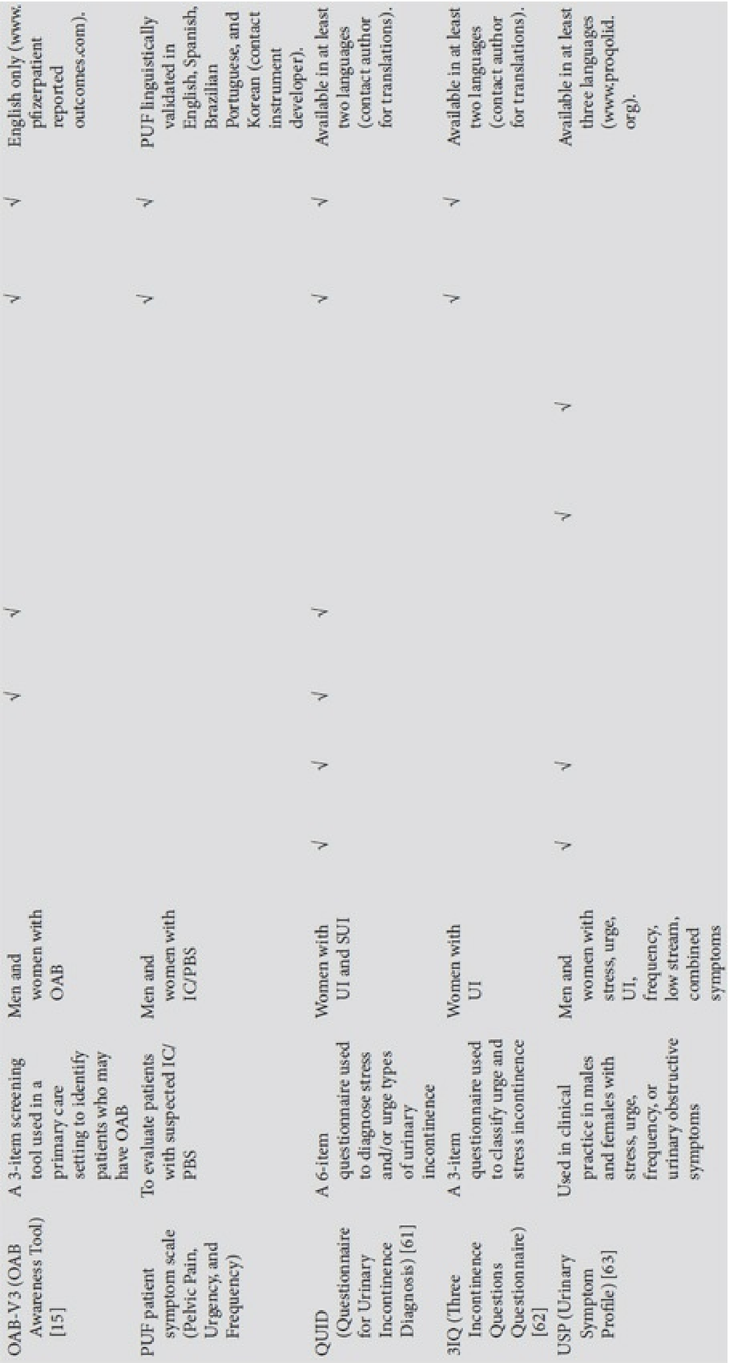
Lower Urinary Tract Symptoms

Bladder Self-Assessment Questionnaire or Bladder Control Self-Assessment Questionnaire

The B-SAQ instrument was developed by a European panel of experts in lower urinary tract dysfunction as a screening tool to evaluate the presence of bothersome LUTS in women [5]. The final instrument was validated and showed good reliability, validity, and sensitivity/specificity. The questionnaire has been translated and validated in at least 14 languages and is for both men and women.

Table 14.1 LUTS Screeners Overview

PRO name	Purpose of tool	Population sample	Reliability		Validity				Sensitivity/ specificity	Validation in other languages	Available languages
			Internal consistency	Test–retest	Content	Criterion	Concurrent	Discriminant			
B-SAQ (Bladder Self-Assessment Questionnaire) or Bladder Control Self-Assessment Questionnaire (BCSQ) [5]	A screening tool for the presence of bothersome lower urinary tract symptoms (LUTS) in women	Women	√	√		√	√	√	√	√	Available in at least 14 languages (contact author for translations).
ICSI (Interstitial Cystitis Symptom Index) [8]	A screening tool for interstitial cystitis (IC) and pelvic pain syndrome (PBS)	Women	√	√	√		√	√		√	Available in at least three languages (contact author for translations).
ISQ (Incontinence Screening Questionnaire) [58]	A 5-item questionnaire developed to screen for incontinence in women	Women with UI		√				√		√	None found
MESA (Medical, Epidemiological, and Social Aspects of Aging Questionnaire) [11]	A 15-item screening tool for UI in the female pelvic medicine and reconstructive surgery patients	Women with UI		√						√	Available in at least two languages (contact author for translations).
OAB-SS (Overactive Bladder Symptom Score) [59]	A 7-item questionnaire validated to measure overall symptom severity due to the four index symptoms of OAB	Men and women with LUTS, with or without OAB	√	√	√			√	√	√	Available in at least five languages (contact author for translations).
OAB-V8 (OAB Awareness Tool) [60]	An 8-item screening tool used in a primary care setting to identify patients who may have OAB	Men and women with OAB			√	√			√	√	OAB-V8 is linguistically validated into 29 languages (www.pfizerpatientreportedoutcomes.com).



OAB-V3 (OAB Awareness Tool) [15]	A 3-item screening tool used in a primary care setting to identify patients who may have OAB	Men and women with OAB			√	√			√	√	English only (www.pfizerpatientreportedoutcomes.com).
PUF patient symptom scale (Pelvic Pain, Urgency, and Frequency)	To evaluate patients with suspected IC/PBS	Men and women with IC/PBS							√	√	PUF linguistically validated in English, Spanish, Brazilian Portuguese, and Korean (contact instrument developer).
QUID (Questionnaire for Urinary Incontinence Diagnosis) [61]	A 6-item questionnaire used to diagnose stress and/or urge types of urinary incontinence	Women with UI and SUI	√	√	√	√			√	√	Available in at least two languages (contact author for translations).
3IQ (Three Incontinence Questions Questionnaire) [62]	A 3-item questionnaire used to classify urge and stress incontinence	Women with UI							√	√	Available in at least two languages (contact author for translations).
USP (Urinary Symptom Profile) [63]	Used in clinical practice in males and females with stress, urge, frequency, or urinary obstructive symptoms	Men and women with stress, urge, UI, frequency, low stream, combined symptoms	√	√			√	√			Available in at least three languages (www.proqolid.org).

Pelvic Pain Syndrome and Interstitial Cystitis

There are two commonly used screeners for pelvic pain syndrome (PBS) and IC, the Interstitial Cystitis Symptom Index (ICSI) and Pelvic Pain and Urgency/Frequency (PUF) questionnaire. Researchers evaluated the ability of the PUF along with the ICSI to screen for IC/PBS among patients attending a urology clinic prior to diagnosis [6]. They found that while both tools could adequately distinguish IC from other urinary tract pathologies and aid in the diagnosis of IC/PBS, neither demonstrated sufficient specificity to serve as a sole diagnostic indicator.

Pelvic Pain and Urgency/Frequency

The PUF questionnaire is an eight-question scale that measures both the severity of IC/PBS symptoms, including pelvic pain, urgency/frequency and dyspareunia, and the degree to which patients are bothered by them [7].

A score of 13 or greater was found to provide the best sensitivity/specificity ratio for the PUF.

Although the PUF was developed to be patient reported, its content was developed by clinicians without patient input. While the scale provides good coverage of the key symptoms of IC/PBS, it includes clinical language such as "urethra" and "perineum," which may not be well understood by patients. Additionally, the layout of the questions may be confusing to patients. Thus, the validity of the PUF as a patient-reported, symptom-based diagnostic tool remains in question.

Interstitial Cystitis Symptom Index

The O'Leary-Sant ICSI assesses global IC symptom severity, with scores ranging from 0 to 20. This is based on four questions that measure the severity of day- and nighttime urinary frequency, urgency, and bladder pain over the past month [8]. The content of the questionnaire was developed from literature review, patient focus groups, and input from clinicians with expertise in the diagnosis and treatment of IC. Internal consistency and test–retest reliability were found to be high for the scale. The ICSI has been further validated as an IC/PBS symptom measure in a randomized, double-blind clinical trial [9]. In addition to good test–retest reliability, internal consistency, and construct validity, the ICSI was found to be responsive to change. A score of 0–6 has been suggested as indicative of mild symptoms, 7–14 of moderate symptoms, and 15–20 of severe symptoms [10].

Urinary Incontinence

Medical, Epidemiological, and Social Aspects of Aging Questionnaire

The Medical, Epidemiological, and Social Aspects of Aging questionnaire is a 15-item tool developed to screen for urinary incontinence and other urinary symptoms in noninstitutionalized women [11]. Frequency of symptoms is measured on a 4-point scale from "never" to "often" with higher scores indicating more frequent symptoms. There are two subscales: six items that assess stress incontinence and nine items for urge incontinence and other urinary symptoms; each subscale was rescored to have a range from 0 to 100 [12].

Overactive Bladder

OAB Awareness Tool V8 and V3

The OAB-V8/OAB awareness tool has been adapted from the Overactive Bladder Questionnaire (OAB-q), which is a 33-item questionnaire, that assesses symptom bother and HRQL impact of OAB [13]. The OAB awareness tool V8 and V3 are an 8-item and a 3-item questionnaires, which evaluate the symptoms of OAB. Responses are graded on a 6-point Likert scale. Patients with an overall score of eight or more on the V8, or four or more on the V3, are directed to seek medical advice. These questionnaires have been validated for use by men and women [14,15].

Sexual Dysfunction (Refer Also to Chapter 64)

There are several screeners that can be used to detect sexual dysfunction. PRO questionnaires have been developed to detect hypoactive sexual desire disorder (HSDD), female sexual arousal disorder (FSAD), female orgasmic disorder (FOD), and satisfaction and pain on intercourse (dyspareunia). Table 14.2 provides an overview of sexual dysfunction questionnaires: their validity, reliability, and availability.

Hypoactive Sexual Desire Disorder Screener

The 4-item HSDD screener was developed to screen specifically for the presence or absence of HSDD in women 18 years and older [16]. Three of the items address desire and one item addresses level of distress. The HSDD screener was developed and validated on women with HSDD as confirmed by clinician diagnosis. The HSDD is self-administered in approximately 2 minutes and has a 5-point Likert scale and a 3-month recall period.

Female Sexual Function Index

The Female Sexual Function Index (FSFI) is a 19-item questionnaire. It has been developed as a brief self-report instrument for assessing sexual function in women [17].

It was developed on a female sample of normal controls and age-matched subjects and provides scores on six domains of sexual function (desire, arousal, lubrication, orgasm, satisfaction, and pain) as well as a total score. The FSFI has been validated on clinically diagnosed samples of women with

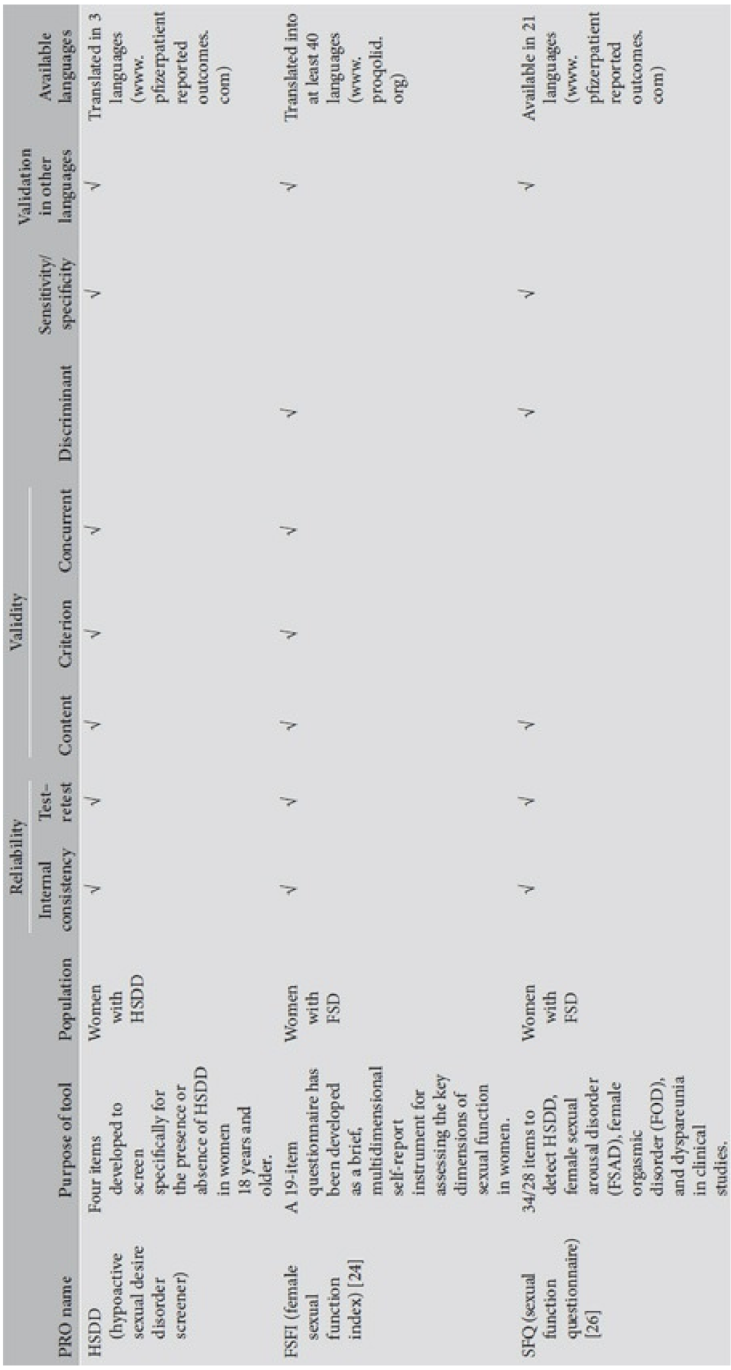
FSAD, FOD, and HSDD [18].

Sexual Function Questionnaire

The Sexual Function Questionnaire (SFQ) developed by Quirk et al. was designed to detect HSDD, FSAD, FOD, and dyspareunia in clinical studies [19]. Further validation of the SFQ was undertaken to determine its usefulness as a screener. The research has demonstrated that the SFQ can distinguish between the presence and absence of specific female sexual dysfunction (FSD) symptoms in a large sample of different clinical populations [20]. The original SFQ consisted of 34 questions in two scales, one on sexual activity and the other on sexual life with a 4-week recall period.

The original questionnaire was shortened to a 28-item SFQ28, which was developed as a screening tool for FSD and also as an efficacy measure in women 18 years and older [27]. The SFQ28 has 6 domains, four of which are specific to the four main types of FSD: FSAD, FOD, HSDD, and pain disorder. The other two domains address “enjoyment” and “partner” issues. The instrument was developed and validated in a broad spectrum of women with FSD. The SFQ is self-administered in approximately 10 minutes and has a 5-point Likert scale and a 4-week recall period.

Table 14.2 Sexual Dysfunction Screeners Overview



PRO name	Purpose of tool	Population	Reliability		Validity						
			Internal consistency	Test-retest	Content	Criterion	Concurrent	Discriminant	Sensitivity/ specificity	Validation in other languages	Available languages

MEASURING PATIENT SATISFACTION AND EXPECTATIONS

Background

Patient satisfaction is the subjective, personal evaluation of treatments, health service, and health-care providers. Although frequently reduced to a single, one-dimensional item in clinical practice “Are you satisfied with your treatment?” satisfaction with medical treatment represents a complicated construct, which includes efficacy, side effects, accessibility/convenience, availability of resources, continuity of care, cost, availability of information on the disease, information giving, and pleasantness of surroundings and quality/competence of health-care providers [21]. At its most basic level, satisfaction is a comprehensive evaluation of several dimensions of health care based on patient expectations and provider and treatment performance.

As an outcome measure, patient satisfaction allows health-care providers to assess the appropriateness of treatment according to patient expectations. Although the importance of patient satisfaction assessment is often ignored, it plays a key role in assessing outcomes. In chronic diseases, where patients must live with treatment, patient satisfaction may be the distinguishing outcome [22]. Evidence suggests that patient satisfaction may be more sensitive to change than the quality of life in clinical trials in chronic diseases [23].

Satisfaction with treatment provides information on treatment effectiveness [24] and is believed to affect clinical outcome [25]. It has been shown that high levels of patient satisfaction with medication correlates with treatment compliance, maintenance of a relationship with a specific provider, and disclosure of important medical information [26]. High levels of satisfaction have also been positively associated with good health status, fewer medical encounters, and shorter hospital stays [27]. In contrast, dissatisfaction with medication may impact a patient's likelihood to register formal complaints about services, engage in legal action against a clinic or provider, or provide unfavorable publicity about a clinic [28]. Preliminary work that suggest satisfaction with pain treatment can influence patient behavior, particularly regarding their intention to continue to take medications [29].

Satisfaction, if measured correctly, differs from other patient-reported, clinician-reported, and objective outcome measures, in that it addresses the influence that expectations can have on satisfaction. For instance, health status instruments measure the outcomes of treatment (whether they be physiological, symptoms, or impact); satisfaction assessments measure the level of satisfaction with these outcomes, given a level of expectations about treatment outcome. The role that expectations play in satisfaction assessments cannot be minimized: a patient with high expectations for treatment outcome may remain dissatisfied even after "successful" treatment because the patient's expectations for treatment benefit were not in alignment with what could be reasonably expected in terms of efficacy. Similarly, a patient with low expectations for treatment benefit can end up extremely satisfied with the treatment regardless of whether or not it worked simply because any treatment benefit, even small, is seen as meeting low expectations. Although the role of expectations in satisfaction assessments cannot be ignored, they can be accounted or controlled for by ensuring that patient expectations are measured at the time a patient initiates treatment.

As in other areas, the use of satisfaction assessments in clinical practice can provide complementary information to other PRO measures and provide information that may be useful in understanding why a patient may or may not remain adherent to treatment.

There are both generic- and condition-specific questionnaires to assess patient satisfaction with urogynecological treatment. There are three generic questionnaires (the Treatment Satisfaction Questionnaire for Medication [TSQM], Benefit, Satisfaction, and Willingness [BSW], and Satisfaction with Medication Questionnaire [SATMED-Q]) and three condition-specific measures (the Global Ratings of Patient Satisfaction and Perceptions of Improvement, the Overactive Bladder Satisfaction with Treatment Questionnaire [OAB-SAT-Q], and the Overactive Bladder Treatment Satisfaction Questionnaire [OAB-S]) that are measures for OAB. Of the three measures, only the OAB-S adequately addresses the role of expectations in satisfaction assessments. Further, the OAB-S examines the tolerability of medications (focused on antimuscarinic treatments) in a more comprehensive manner than the OAB-SAT-Q. Generally, responsiveness cannot be assessed as there is no baseline assessment of patient satisfaction with treatment as no treatment has been given. Here, Table 14.3 presents a summary of generic and disease-specific satisfaction instruments identified in urogynecology and their reliability, validity, and availability.

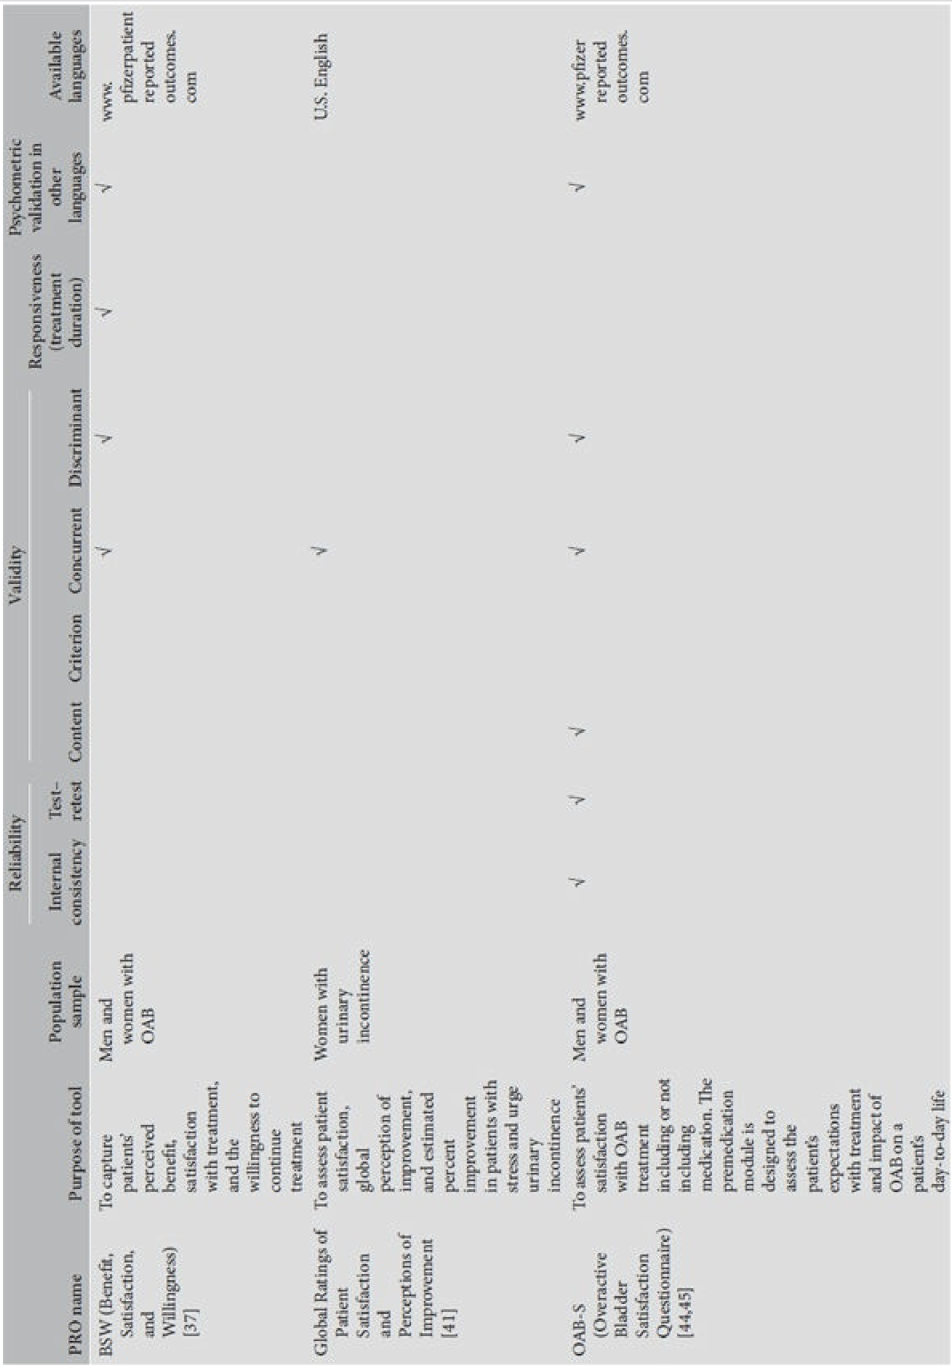
Benefit, Satisfaction, and Willingness Questionnaire

This three-item questionnaire is designed to assess treatment benefit, patient satisfaction with treatment, and patient willingness to continue treatment. The BSW questionnaire was validated using data from three 12-week placebo-controlled trials of tolterodine in patients with OAB [30]. In this validation, study correlations were seen between patient-reported treatment satisfaction and improvements in the OAB-q, KHQ, and micturition variables.

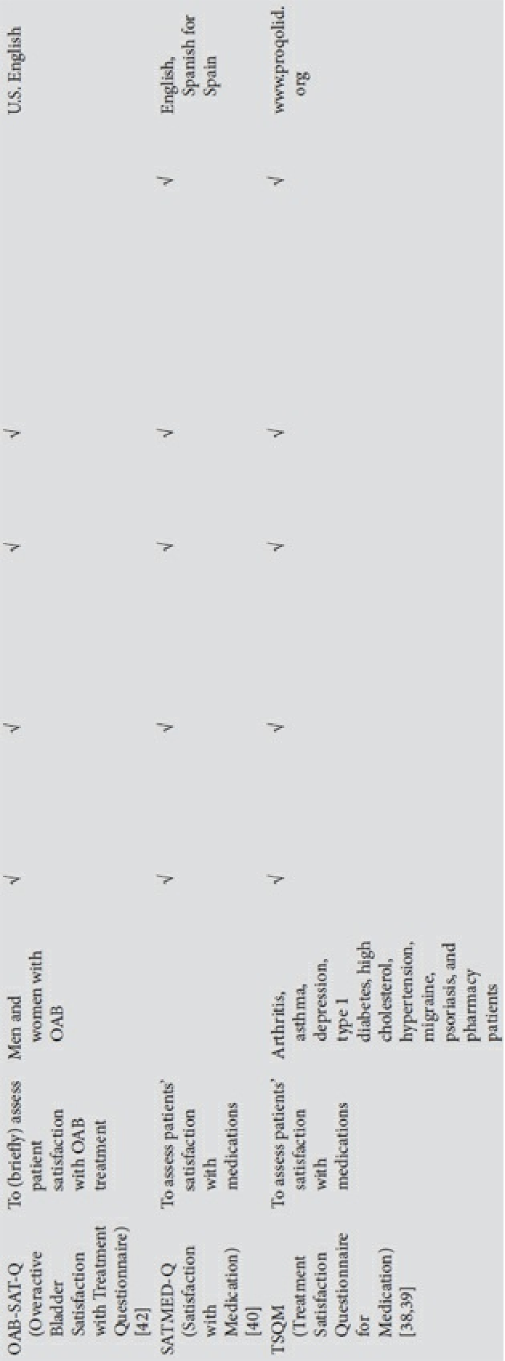
Treatment Satisfaction Questionnaire for Medication

The TSQM is a general measure of treatment satisfaction with medication suitable for use in a wide variety of medication types and illness conditions. Version 1 of the questionnaire contains four scales: side effects (three items), effectiveness (three items), convenience (three items), and global satisfaction (three items). It has been demonstrated to be a psychometrically sound and valid measure of patients' satisfaction with medication [31]. Version 2 of the questionnaire is slightly shorter [32]. Psychometric tests of the two measures have shown that they perform equivalently when predicting measures of concurrent validity.

Table 14.3 Summary of Urogynecological PRO Measures of Patient Satisfaction



PRO name	Purpose of tool	Population sample	Reliability		Validity				Responsiveness (treatment duration)	Psychometric validation in other languages	Available languages
			Internal consistency	Test-retest	Content	Criterion	Concurrent	Discriminant			
BSW (Benefit, Satisfaction, and Willingness) [37]	To capture patients' perceived benefit, satisfaction with treatment, and the willingness to continue treatment	Men and women with OAB					√	√	√	√	www.pfizerpatientreportedoutcomes.com
Global Ratings of Patient Satisfaction and Perceptions of Improvement [41]	To assess patient satisfaction, global perception of improvement, and estimated percent improvement in patients with stress and urge urinary incontinence	Women with urinary incontinence					√				U.S. English
OAB-S (Overactive Bladder Satisfaction Questionnaire) [44,45]	To assess patients' satisfaction with OAB treatment including or not including medication. The premedication module is designed to assess the patient's expectations with treatment and impact of OAB on a patient's day-to-day life	Men and women with OAB	√	√	√		√	√		√	www.pfizerreportedoutcomes.com



OAB-SAT-Q (Overactive Bladder Satisfaction with Treatment Questionnaire) [42]	To (briefly) assess patient satisfaction with OAB treatment	Men and women with OAB	✓	✓	✓	✓		U.S. English
SATMED-Q (Satisfaction with Medication) [40]	To assess patients' satisfaction with medications		✓	✓	✓	✓	✓	English, Spanish for Spain
TSQM (Treatment Satisfaction Questionnaire for Medication) [38,39]	To assess patients' satisfaction with medications	Arthritis, asthma, depression, type 1 diabetes, high cholesterol, hypertension, migraine, psoriasis, and pharmacy patients	✓	✓	✓	✓	✓	www.proqolid.org

Satisfaction with Medication Questionnaire

The SATMED-Q is a 17-item questionnaire with six dimensions: treatment effectiveness, convenience of use, impact on daily activities, medical care, global satisfaction, and undesirable side effects. The SATMED-Q has been demonstrated to be a reliable and valid measure of treatment satisfaction; however, the sensitivity to change has yet to be established [33].

Global Ratings of Patient Satisfaction and Perceptions of Improvement

The Global Ratings of Patient Satisfaction and Perceptions of Improvement questionnaire is a three-item questionnaire that assesses patient satisfaction with treatment, the patient's perception of change, and the patient's estimated percent improvement following an intervention [34]. All questions are global in nature and do not examine particular aspects of changes in health outcomes. The measure has undergone limited psychometric testing and only the concurrent validity of each item compared to the other items has been conducted.

Overactive Bladder Satisfaction with Treatment Questionnaire

The OAB-SAT-Q is a brief 11-item questionnaire, which measures satisfaction, side effects, endorsement (e.g., willingness to use the same treatment), convenience, and preference. Internal consistency reliability were good (Cronbach's alpha 0.84–0.95), Subscale correlations were good and the measure has demonstrated good discriminant validity [35]. The measure has been shown to be responsive and sensitive to treatment differences and changes [36].

Overactive Bladder Treatment Satisfaction Questionnaire

The OAB-S is a five-domain questionnaire, which evaluates control expectations, impact on daily living with OAB, OAB control, fulfillment of OAB medication tolerability, and satisfaction with control. Internal reliability coefficients were good (Cronbach's alpha 0.76–0.96), test–retest reliability has been established (reliability coefficients 0.72–0.87) [37,38], and known groups have been validated. Cultural and linguistic differences were considered early in the development process, and the OAB-S is available in over sixteen languages [39].

GOAL ATTAINMENT SCALING

Background

Goal attainment scaling (GAS) was first introduced in the 1960s by Kiresuk and Sherman [40]. It was created to assess health outcomes in mental health settings, but has in recent years been expanded to other therapeutic areas. This technique is used to measure clinically important change in numerous settings, especially those that require an individualized and multidimensional approach to treatment planning and outcome. Most notably, GAS has been used to assess drug trials for the treatment of Alzheimer's disease [41,42] and has been recently expanded to include evaluations in urogynecology [43,44]. The advantage that GAS offers is that it may be more responsive to change in some instance: GAS has been found to be more responsive to change than the measures commonly used in evaluating effectiveness of specialized intervention [45], but it requires additional investigation in the area of OAB [46]. The validity and reliability of GAS has been demonstrated in the areas of OAB [47], elderly care [48], chronic pain [49], and cognitive rehabilitation [50].

GAS differs from traditional quality of life measures and satisfaction assessments in several ways. First, it represents an individualized approach to measurement that augments information gained from standardized outcome measures. The chief weakness to standardized PRO measures is that it requires that patients answer a fixed set of questions—essentially a "one-size-fits-all" approach to assess quality of life. If the measure is well developed and validated (such as the OAB-q and the OAB-S), it can be assumed that the content is generally relevant to patients; however, even with these measures, there is no adjustment for the individual or a particular situation. Under GAS, the outcome scales are tailored specifically to the individual. Individuals select their own goals for treatment and only rate the symptoms or impacts that they experience: there is no need to rate symptoms or impacts that patients do not care about or never experience. In this sense, GAS represents a patient-centered approach to outcome measurement: only those areas each patient finds important are measured and evaluated.

Second, the role of patient expectations is central to GAS. Under traditional quality of life evaluations, expectations for treatment outcomes are largely ignored. Under satisfaction assessments, the role is made more explicit; however, expectation data in satisfaction assessments are usually only analyzed to determine how much of the change in satisfaction was due to pretreatment expectations vis-à-vis actual treatment efficacy. Under the GAS methodology, the goals or the expectations patients have about treatment benefit are something that is seen to be actively managed. If patients set unrealistic treatment goals and their expectations for treatment benefit can never be achieved, it is up to the health-care provider to separate unrealistic goals from realistic goals and explain to patients what their treatment can actually achieve [51]. In this way, patients are expected to remain adherent to treatment because they understand that some of their goals will never be achieved, while others may be obtained with treatment. For instance, if a patient understands from the outset that their goal of cure is unrealistic, then they may remain happy with a treatment that only alleviates symptoms with few side effects.

The third advantage of GAS is that although it is a very individualized approach to measuring patient-reported outcomes, it may still be employed in clinical trial settings. Although this appears counterintuitive because one patient's goals may differ from another patient's goals both in terms of number of goals and the types of goals, GAS scores may be combined by treatment group into a summary score utilizing standardized z-based scoring. Although GAS should not be used to derive an absolute level of an outcome (a health status score), it can be used to track achievement: at either an individual level or a group level.

GAS involves a multistep approach, which begins with the identification of goals by the patients. Patients are involved in the goal setting and weighting of the importance of goals and communicating the goals to their health-care provider [52]. At the initial assessment, patients list their goals and the importance of each goal to them (for example, 1, fairly important; 2, very important; and 3, extremely important; the score of 0 is not allowed because that would mean that the goal was not important to the patient and therefore not necessary to be included in the list of goal). For the next step, anticipated or expected outcome levels are discussed by patients with their health-care provider: goals that are unrealistic may be eliminated and the health-care provider resets patient expectations for treatment benefit. Finally, a time for the assessment of treatment goal attainment is determined. During this assessment period, goal attainment is rated according to the following: if the goal was achieved as predicted, this is scored 0, achievement above the level predicted is scored at +1 (“somewhat better than expected or predicted”) or +2 (“much better than expected or predicted”), no change or achievement below the expected level is scored as −1, and a worsening of the target function is scored as a −2.

Goal achievement has been used in several studies in the area of urogynecological conditions. The studies are best described as preliminary investigations into how goal setting and attainment play a role in this area. The use of GAS in urogynecological conditions is developing rapidly, and the usefulness, validity, and reliability in these conditions are still being evaluated.

The earliest investigation was by Hullfish et al. [53] In this study, patients were asked to describe 5 personal goals for pelvic floor surgery, which were rated on a 5-point scale. After surgery (3 months, 1 and 3 years), patients assessed their goals and either agreed or disagreed that the goals were met. Agreement was rated as +1 and strong agreement was rated as +2, disagreement was rated as −1, and strong disagreement was rated as −2. The validity of the assessment in pelvic floor surgery was partially established by relating Incontinent Impact Questionnaire and the Urogenital Distress Inventory scores to goal achievement.

Elkadry and others [54] found that women’s goals for reconstructive pelvic surgery are personal and highly subjective and that the decision to undergo surgery is based on specific patient-selected goals. In a follow-up to this work, Mahajan et al. [55] examined goals and satisfaction in an urge incontinence population. Patients were asked to list their goals and at follow-up patients were asked to identify the degree to which each goal was achieved 1 year post surgery (completely to not at all). The study found that failure to meet goals was associated with long-term dissatisfaction with surgery.

In the area of IC/painful bladder syndrome, GAS has been employed to determine whether patients’ treatment goals are unique [56]. This study found over 140 separate goals with a mean number of 4 goals per patient with pain, frequency, and nocturia being the most frequently described goals. Based on these findings, a new GAS instrument is in development in this area.

In the area of drug treatment for urgency and urge incontinence, goal improvement was evaluated in women treated with transdermal oxybutynin or placebo [53]. The most frequently reported goals were in the areas of urgency (“not rushing to the toilet when I hear taps”), nocturia (“not to get up so much at night”), and frequency (“need to go to the toilet less than I do”) [54]. This study found that after 4 weeks of treatment, goal achievement was only slightly higher for transdermal oxybutynin (42%) vs. placebo (32%) with other measures showing only limited convergence with goals [53,54].

In the area of OAB and LUTS, a new measure of GAS has been developed: the Self-Assessment Goal Achievement (SAGA) questionnaire [50]. Due to the fact that early research found that some patients have difficulty formulating goals, interviews with LUTS patients were conducted to identify the most bothersome symptoms. These symptoms were incorporated in the first part of the SAGA tool as a fixed assessment of nine symptom goals. In the second part of SAGA, in line with traditional GAS measures, patients can record any other goals that they have related to their LUTS. At follow-up, patients rate the level of goal achievement on each of the goals they selected. The validity of the measure in clinical practice has recently been demonstrated [57].

CONCLUSION

The accurate and proactive screening for urological conditions should play an increasing role in improving health care. Additionally, the importance of understanding patient expectations, goals, and satisfaction is increasingly recognized as a critical element in judging overall outcomes in urogynecological conditions. The increasing availability of validated PRO screeners that can assist clinicians and researchers with assessing symptoms and conditions has the potential to greatly enhance communication among clinicians and patients, as well as among researchers. Validated tools that assist with assessing expectations, goal setting and achievement, and measurement of satisfaction can be incorporated into clinical and research practice. This is a high-impact area for continued research as clinicians and patients alike seek to improve their understanding of each other's expertise and seek mutually reasonable treatment plans that results in satisfied patients with an improved quality of life. This chapter should facilitate inclusion of appropriate PRO screening and outcomes tools as part of routine assessment in clinical practice. In future urogynecological research, measuring expectations, satisfaction, and goal attainment as primary or coprimary outcomes should be considered as part of a complete assessment of urogynecological treatment.

15 Questionnaires to Assess Sexual Function

Claudine Domoney and Tara Symonds

Patient-reported outcome (PRO) measures to assess sexual function are perhaps those of most significant value as this sphere of activity is one of the most difficult in which to capture information that is meaningful. These instruments, if designed well, may incorporate the functional aspects of sexuality, the symptom severity, and the impact on quality of life. The WHO has defined sexual health as a state of physical, emotional, mental, and social well-being in relation to sexuality (and), not merely the absence of disease, dysfunction, or infirmity [1], and therefore an important reflector of global well-being. However, there are great differences in the perception of clinicians and patients when discussing sexual outcomes. What is important for the patient may not be easily communicated to the doctor. Monitoring the effect of treatment or interventions on sexual parameters has generally been relatively crude to date. Questions that appear comfortable for doctor and patient to discuss may have little bearing on the true change in sexual activity. The varied urogynecological population, whose sexual backgrounds may be diverse, need determination of the most appropriate method of measuring the desired data. As 11% of women have surgical treatment for pelvic floor dysfunction (PFD) [2], this is the time to properly determine the impact of the disease process and its treatment on sexual function.

WHY USE QUESTIONNAIRES?

Traditionally, gynecologists and urologists have asked questions to their patients pertaining to sex, which are comfortable for both to ask and answer. The enquiry may be directed to areas perceived by clinicians as influenced by the disease or condition and that may reasonably be expected to improve with intervention. These include sexual activity, often phrased as frequency of penetrative vaginal intercourse, and pain or dyspareunia. More qualitative components of sexual function may be more difficult to assess unless posed in a questionnaire format. Asking about orgasm frequency or quality, satisfaction, arousal, and sexual desire may be difficult for both clinicians and patients, particularly if they perceive they have had inadequate training [3,4]. As these factors frequently vary between couples depending on the length and quality of relationship, the age of both partners, and the menopausal or peripartum status, a questionnaire that is sensitive enough to determine these factors may be important if trying to assess the impact of an intervention such as surgery.

It is likely that issues of lesser concern to individuals were previously focused on, and this underestimates the true incidence of sexual difficulties. At present, it appears anatomical vaginal measurements in urogynecological patients do not predict function [5]. Investigations such as urodynamic measures, pelvic blood flow, 4D ultrasound, vaginal plethysmography, and nerve conduction studies may give quantitative values to compare population or study groups, but the evaluation of their relationship to sexual function is in its infancy. Whether they will ever graduate to useful clinical measurements with respect to sexuality is arguable. “The vagina may say yes but the mind says no”—physical measures to assess the state of arousal such as blood flow and lubrication do not reproducibly correlate with subjective sense of arousal in women.

PFD is common with up to one-third of premenopausal and half of postmenopausal women having some form of PFD, which may then lead to a reduction in quality of life, the most important outcome. However, sexual problems are also highly prevalent, with a North American study reporting that up to 43% of women and 31% of men aged between 18 and 59 admitted a problem in the previous year [6]. British studies have indicated that the prevalence of sexual problems in primary care is high with 22% of men and 40% of women being diagnosed with a sexual dysfunction, although this was poorly recognized and documented [7]. However, when the degree of distress or “bother” is considered by clinicians, the proportion with a sexual problem approximately halves in many studies [8]. Clearly, it is important for the pelvic surgeon to be able to evaluate the changes in PFD that prevent sexual activity or reduce satisfaction from those that are common in the general population. Questionnaires that are sensitive enough to detect these differences and the modification that can be expected from urogynecological interventions may help individual patients and studies.

FEMALE SEXUAL FUNCTION

Designing instruments to measure sexuality requires a model to promote the understanding of female (and male) sexuality and its deviations. Over the twentieth century, models of human sexual behavior have been proposed, and its classification of normal and abnormal became clinical measurable entities. However, the norms for function and activity are varied, and at present, there is a debate over how medicalization of human sexual behavior has been propagated by the prospect of pharmaceutical intervention. Yet, there is also a drive from women as expectation of a full and satisfying sexual life has been raised, with over half of one study of 1805 European menopausal women stating it was important [9]. Many other international studies of older populations reinforce these findings [10,11].

The Masters and Johnson human sexual response cycle model from the 1960s details the changes occurring during sexual activity based on observations from laboratory-based sexual encounters [12]. This has been developed into other models over the last 30 years, but more recently, an International Consensus Group on female sexual dysfunction (FSD) has expanded these female sexuality models to include the importance of intimacy and sexual stimuli on innate sexual drive [13,14]. This contrasts to the linear human sexual response model of Masters and Johnson more in keeping with male sexuality, having an inbuilt sexual drive, i.e., libido and desire to be involved in sexual behavior that precedes excitement and arousal. Women, in contrast to men, may only achieve orgasm in 50% of penetrative intercourse and a further 20% with external stimulation.

The International Consensus Group model of female sexuality indicates that a spontaneous sexual drive to be involved in sexual activity does not need to be present for satisfactory relationships to be maintained. The content of sexual activity of women *may* be less goal driven than that of men. Therefore, it is important to understand the other features influencing an individual woman’s ability to be sexual in order to explain why she may be experiencing difficulties. How much urogynecological complaints contribute to this may not be clear to the clinician or patient themselves. Sexuality is modulated by many factors and normal features of life, including life events, reproductive events, health, relationships, and cultural factors. Female sexuality is a complex interplay of physiological, psychological, and cultural factors. A well-developed questionnaire may be able to detect the effect of PFD on sexual function and activity, its effect on quality of life, and the changes in sexual function after interventions.

FEMALE SEXUAL DYSFUNCTION

At present, the most accepted international definitions of FSD have been determined by the International Consensus Conference panel modification of the framework of the International Classification of Diseases-10 and Diagnostic and Statistical Manual of Mental Disorders (DSM-IV and DSM-V) of the American Psychiatric Association. These areas were defined as four separate categories by DSM-IV, but recently, DSM-V has recategorized desire and arousal disorders as one combined disorder and dyspareunia and vaginismus as genitopelvic pain/penetration disorder, with additional disorders such as aversion disorder female sexual orgasmic disorder or female orgasmic disorder (FOD) and noncoital pain disorders. The quantification of these disorders including the identification and qualification of pain can be adapted for clinical and research settings. Specific dysfunctions can be diagnosed if the domains within an instrument are sufficiently sensitive. Not all instruments are diagnostic of dysfunctions, while others are specific to one disorder, e.g., desire disorder. Before choosing an instrument for use, the outcomes sought should be clarified so fitness for purpose can be ensured. Diagnosing FSD or a specific disorder may not be important and global sexual function the most important issue. Questionnaires may be designed to give a composite score that can be broken down into domains to diagnose or screen for a specific dysfunction (e.g., female sexual function index [FSFI]) or a global score for comparison, with nondiagnostic domains (e.g., prolapse and incontinence sexual questionnaire [PISQ]). Many instruments may have a more “user-friendly”short form for use in clinical practice but are likely to be less sensitive.

FSD in Urogynecology

It is clear that the minority of physicians caring for women with PFDs screen for sexual dysfunction at present. Surveys have reported that this is due to lack of time and treatment options, the older age of many of the patient groups, and the perceived lesser importance of this aspect of functioning [3,4]. However, there is objective evidence that pelvic floor problems adversely affect sexual relationships and sexuality, making it important clinicians are aware of change in functioning. Most studies report that 50%–60% of urogynecology research participants are sexually active. Up to 64% may be labeled with FSD [15], but the degree of distress associated with this is pivotal in the diagnosis of true dysfunction. There is a reluctance on the part of patients to seek help that may be mitigated by the doctors' comfort and ability to communicate about such personal matters. It can be easier for both the doctor and patient to use a questionnaire to detect these difficulties. However, this can also be perceived as an avoidance tactic by surgeons with a different agenda. Questionnaires do help to reduce the time constraint of the doctor–patient interaction by having patients complete the questionnaires while waiting for the consultation or before their clinic visit. Furthermore, in the area of sex, reduction of embarrassment may result in more valuable answers. Yet, as all clinicians would agree, these instruments have no replacement for the consultation and should be interpreted and integrated with the patients' complaints.

Up to 50% of women with urinary incontinence complain of coital incontinence with approximately one-third admitting it compromises their sexual health [16]. This has been reported widely as impacting on quality of life [17], yet surgical cure for this complaint is not always reported to improve sexual function [18]. Similar findings have been reported with pelvic organ prolapse procedures although the huge variation in surgical techniques and individual patient anatomy may be potential confounding factors [19]. Validity and reproducibility may depend on the tools used to measure these outcomes and explain the conflicting results from many urogynecological studies with respect to sex [20].

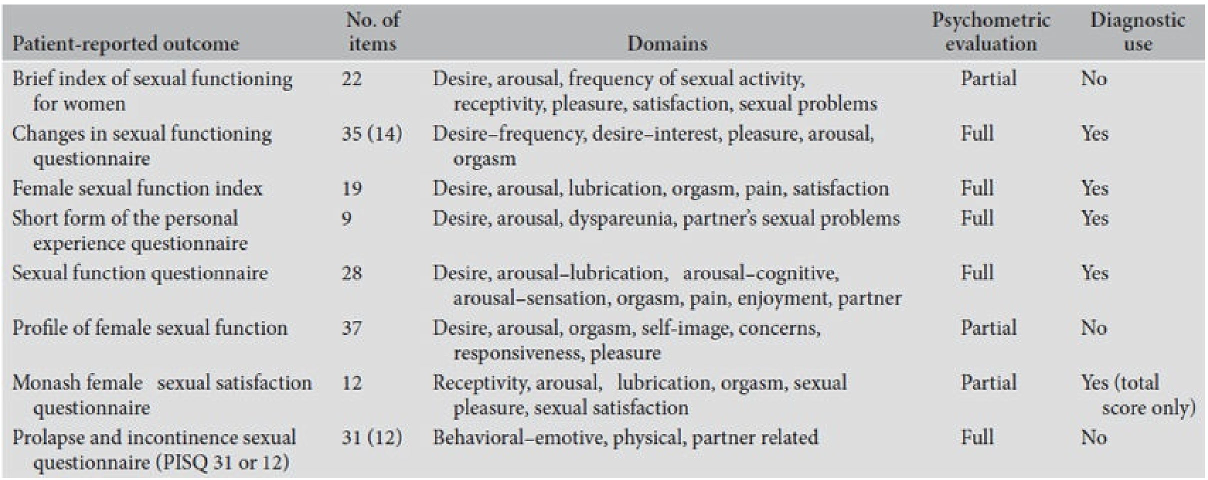
OUTCOME MEASURES

Since the launch of sildenafil in 1998 for the treatment of erectile dysfunction (ED), there has been a significant growth in male and female sexual health research, which has resulted in the development of numerous new assessment measures, both objective and subjective.

Objective Measures

There have been numerous objective measures developed to diagnose and assess erectile function (e.g., Doppler ultrasonography, penile–brachial index [21]), but penile tumescence using Rigiscan has been the most widely used [22]. Diagnosis and assessment of men with premature ejaculation has relied on the use of time (stopwatch assessment) to ejaculation (intravaginal latency time). For women, objective measures have been developed such as vaginal photoplethysmography and Doppler ultrasonography [23]. Objective assessment of sexual function in men with ED shows good agreement with subjective assessments, considered to be because of the obvious biofeedback loop of the rigidity of the penis. However, in women, agreement between the objective and subjective assessments of sexual function has not been easy to demonstrate; this may be due to its being multidimensional compared to the unidimensionality of ED.

Table 15.1 Female Sexual Dysfunction Patient-Reported Outcome Measures



Patient-reported outcome	No. of items	Domains	Psychometric evaluation	Diagnostic use
Brief index of sexual functioning for women	22	Desire, arousal, frequency of sexual activity, receptivity, pleasure, satisfaction, sexual problems	Partial	No
Changes in sexual functioning questionnaire	35 (14)	Desire–frequency, desire–interest, pleasure, arousal, orgasm	Full	Yes
Female sexual function index	19	Desire, arousal, lubrication, orgasm, pain, satisfaction	Full	Yes
Short form of the personal experience questionnaire	9	Desire, arousal, dyspareunia, partner's sexual problems	Full	Yes
Sexual function questionnaire	28	Desire, arousal–lubrication, arousal–cognitive, arousal–sensation, orgasm, pain, enjoyment, partner	Full	Yes
Profile of female sexual function	37	Desire, arousal, orgasm, self-image, concerns, responsiveness, pleasure	Partial	No
Monash female sexual satisfaction questionnaire	12	Receptivity, arousal, lubrication, orgasm, sexual pleasure, sexual satisfaction	Partial	Yes (total score only)
Prolapse and incontinence sexual questionnaire (PISQ 31 or 12)	31 (12)	Behavioral–emotive, physical, partner related	Full	No

Notes: Full, factor analysis for domain structure, internal consistency, test–retest reliability, convergent validity, known-groups validity, and responsiveness. Partial, one or more of the aforementioned were not completed.

Subjective Measures

Subjective measures of sexual health have flourished over the past 10 years. For assessing ED, the gold standard measure is the international index of erectile function [24,25], but for men with premature ejaculation, there is no gold standard equivalent but there are a number of measures to choose from, which were reviewed recently by Althof and Symonds [26]. Assessment of women's sexual health has tended to use sexual inventories, which capture all elements of the DSM-IV female sexual function cycle domains (female sexual arousal disorder [FSAD], FOD, hypoactive sexual desire disorder [HSDD], and pain) (e.g., sexual function questionnaire [SFQ] [27], FSFI [28]; see Table 15.1 for detailed listing of measures).

Clinician Measures

Evaluation of change in sexual function status can be assessed using clinician interview, which benefits from an in-depth discussion of all aspects of the individual's sexual history or problem. However, standardization of an interview is difficult if trying to use this approach in the evaluation of a new treatment and probably has most utility in diagnosis, although even in diagnosis there will be issues with concordance and reliability between clinicians due to the complex diagnostic criteria for FSD. Utian et al. [29] successfully developed a structured diagnostic method for diagnosing FSD, and Derogatis et al. [30] have recently developed a standardized clinician assessment for diagnosing hypoactive sexual desire disorder—women's sexual interest diagnostic interview.

In evaluating the outcome of treatments for both male sexual function and FSD, small lab-based studies have generally relied on an initial clinician diagnosis of sexual dysfunction, followed by an objective assessment. Larger, randomized controlled trials have used similar clinician diagnosis of dysfunction but with subjective measures of outcome due to ease of use.

DIFFICULTIES SPECIFIC TO SEXUAL FUNCTION IN PFD

Neither pelvic floor nor sexual dysfunction is seen as life-threatening disorders and therefore may have been neglected in the past. There is now a priority for assessing patient outcomes rather than that of the clinician attempting to improve health-care provision for these patient groups. Until relatively recently, the only tools available for urogynecologists and urologists to use were generic questionnaires validated in the general population. Prior to the use of these questionnaires that may have previously been considered outside of the remit of surgeons, self-designed items focusing on the clinicians area of interest such as dyspareunia, frequency of penetrative intercourse, and coital incontinence were quantified in the trials. As a result, it is not clear what effect surgical interventions have on sexual functioning as the results are highly variable depending on how and to whom the questions are being asked and over what time frame. The rate of sexual activity and the causes of change needs to include assessment of partner factors, which more often determine sexual activity in a relationship [31]. Pain as an endpoint may be particularly misleading given that it is widely reported by younger women as a significant factor in their sexual problems compared to older women who are more likely to report other physical features of intercourse as problematic. Sixty percent of women in their 30s had intermittent dyspareunia and one-third persistent [32], whereas another study suggested that lubrication was the most important problem for older women [33].

Asking patients about sex is more likely to yield information as sexual difficulties are less often spontaneously reported. However, the use of questionnaires may produce more reproducible answers and less embarrassment. Subjective information can be gathered in an objective manner. If screening is the aim, three simple questions have been shown to be as effective as a detailed interview [34]:

1. Are you sexually active? (Or are you in a sexual relationship?)
2. Are there any problems?
3. Do you have any pain with intercourse?

Pain may be interpreted as physical but be either physical or psychosomatic—for many patients, these are not distinguishable.

A more sophisticated instrument should aim to clarify the presence of symptoms, their severity, and/or frequency. In addition, it should assess how the patient feels and its impact on the activities of daily living and social, psychological, and emotional well-being. Condition-specific questionnaires will further assess the impact of the condition on function. Therefore, general and condition-specific questionnaires seek different endpoints. Generic questionnaires may elucidate the differences in various conditions and allow comparison with control populations without the condition, whereas condition-specific questionnaires will ideally be designed to elucidate the small differences in patients with a condition such as PFD [35]. This may be further distinguished in PFD sufferers such as the comparison between those with urinary incontinence and fecal incontinence, depending on the validation of the instrument. Sexual function measurement with nonvalidated tools leads in inaccurate and inconsistent results.

Questions within other condition-specific quality-of-life measures may be validated but yield limited information about sexual function and activity such as the King’s health questionnaire (KHQ) and the Incontinence Impact Questionnaire (IIQ). If questions regarding global functioning and quality of life are the endpoints of interest and/or more likely to be acceptable to the patient group, this may be more appropriate but the information and conclusions regarding sexual functioning are more limited.

When developing these tools, it is also important to determine how often these questions will be avoided and how easily they can be misinterpreted as with sexual function. This will have a profound impact on the results obtained. During the validation process or in a paid clinical trial, subjects may be more inclined to answer intrusive questions than in general clinical practice. If questions are routinely not answered or if questionnaires are left substantially incomplete (e.g., because the first question asks about penetrative intercourse without stipulating that further questions do not rely on the presence of a partner), the tool will be effectively useless. Additionally, most questionnaires available are only validated in heterosexual relationships.

If the group that are sexually inactive secondary to their pelvic floor problems are excluded, the proportion that will show improvement will not be readily determinable. The recognition of the importance of length of recall regarding the previous sexual intercourse and/or activity when choosing a tool is imperative. One month, three months, or six months are the usual time frames, and some are clearly inappropriate in some settings such as perioperatively. Yet, for those women having sexual intercourse twice a month (the median frequency for British heterosexual couples aged 45–55 years [36]), although the quality may be more important than quantity, the weighting of frequency in the score could potentially wrongly determine FSD.

With respect to urogynecological problems, it is useful to evaluate other confounding factors including age, menopausal status, possibly the length of relationship, and partner functionality. The perception of the partner as reported by the index patient can have a bearing on function as women tend to protect their sexually dysfunctional partners by developing a corresponding dysfunction such as loss of desire to mask their partners’ inability to maintain an erection or ejaculation.

DEVELOPMENT OF SEXUAL FUNCTION MEASURES

Developing useful questionnaires is an involved and expensive process. The initial process of conceptualization requires the input of clinician and patient. The fundamentals of survey questions require item development and evaluation. It can be argued that the only valid perspective is that of the patient, but if the instrument is to be used by surgeons, it needs to incorporate factors of relevance to their practice. A clinician judging the impact of an operation may want to know that a woman has a noncoital pain disorder such as vulvodynia only to be able to counsel that she is unlikely to be cured of this complaint by her prolapse surgery.

The words used in the items need to be appropriate to ask or identify the same aspect of behavior that the clinician is interested in. The shared understanding may need to be tested in focus groups, particularly with respect to sex where both clinicians and patients use surrogate phrases. An example may be the use of the word libido that for many lay people means all aspects of sexual function—desire, arousal, and erection. The words, sentences, and response choices used need to be clear. Simpler, shorter questions with depersonalized answers to sensitive issues are more likely to produce answers that patients are willing to divulge.

Any instrument requires validation and also reliability testing (content/face, construct, and criterion—see Chapter 12 on PRO development). Further validation is recommended in distinct cultural groups since sex/sexual relationship is especially culturally determined.

QUESTIONNAIRES TO ASSESS FEMALE SEXUALITY

Over the years, both generic and condition-specific measures have been developed for assessing sexual (dys)function in men and women; the following text is an overview of some of the generic measures, condition-specific measures for assessing FSD, and disease-specific measures for use in PFD.

Generic

The Derogatis inventory of sexual functioning [37] and the Golombok Rust inventory of sexual satisfaction [38] are earlier measures designed to capture the essence of sexual behavior and sexual dysfunction in both men and women. However, with the surge in research looking to develop suitable pharmacological treatment(s) for FSD, a number of simple PROs have been developed over the past 10–15 years and are summarized in Table 15.1.

The brief index of sexual functioning for women (BISF-W) [39,40], a 22-item measure, was developed for use in large clinical trials and assesses a number of concepts: thoughts/desire, arousal, frequency of sexual activity, receptivity/initiation, pleasure/orgasm, relationship satisfaction, and problems affecting sexual function. It covers a wide range of concepts and assesses the two main sexual dysfunctions—desire and arousal—but validation of the measure is questionable. A follow-up study by Mazer has produced a new scoring algorithm but needs further validation.

The changes in sexual functioning questionnaire (CSFQ) were designed to measure illness and medication effects on sexual functioning [41,42]. There are male and female versions. The female version comprises 35 items, forming five domains: sexual desire/frequency, sexual desire/interest, sexual pleasure, sexual arousal, and sexual orgasm. The CSFQ can assess sexual functioning in both clinical and nonclinical samples, particularly depressed patients, and has shown sensitivity to change [43]. A short form (14 items) was developed and validated to allow easier use in clinical practice [44].

Condition-Specific FSD Measures

The FSFI was developed by an international panel of experts to apply to all types of FSD and was initially validated in an FSAD population [28]. Meston [45] has since shown its validity in women with FOD and HSDD. The FSFI can also be used to classify women with and without sexual dysfunction [46] and, more recently, women with and without HSDD [47]. This was the first measure to show validity across the differing FSD subtypes rather than just in a general dysfunctional group and as such has been used in a number of studies to assess outcome (e.g., Blumel et al. [48]; Bradford and Meston [49]; Ito et al. [50]; Derogatis et al. [51]). It has frequently been used in PFD studies.

The Short Personal Experiences Questionnaire was adapted from the Personal Experiences Questionnaire and was developed to capture the components of female sexual function for menopausal women desire, arousal, dyspareunia, and also an assessment of partner’s sexual problems [51,53]. The measure was subsequently validated in a group of sexually active women, women with a sexual dysfunction, and women attending a psychiatric clinic [52]. However, the number of subjects was small, $n = 115$, $n = 17$, and $n = 16$, respectively, and particularly draws into question the robustness of the cutoff score to indicate sexual dysfunction.

The SFQ was developed using extensive input from women with a sexual dysfunction ($n = 22$) and from those who were sexually functional ($n = 60$). Additionally, the interviews were conducted across seven countries (the United Kingdom, the United States, Australia, the Netherlands, Denmark, France, Italy) to determine whether cultural background affected the way women described their sexual health/function; consistency of reporting was found. Comprehensive validation resulted in 28 items assessing the following concepts: desire, arousal and lubrication, arousal and sensation, orgasm, pain, enjoyment, and partner [27] The SFQ has also been developed to screen for likelihood of sexual dysfunction, across each of the functional domains (desire, arousal and lubrication, arousal and sensation, orgasm, pain) [54,55]. The confirmation of the pain cutoff scores is required because there were few women with sexual pain used in the assessment. An abbreviated 15-item version is also available.

The profile of female sexual dysfunction was developed through patient interviews and focus groups with women from Europe and North America and who were either naturally or surgically postmenopausal and had low desire [56]. The measure was then further evaluated multinationally in surgically menopausal women with HSDD. Item analysis resulted in seven domains (sexual desire, arousal, orgasm, sexual pleasure, sexual concerns, sexual responsiveness, and sexual self-image) across 37 items. The validity and reliability of the profile of female sexual function in naturally menopausal women with HSDD have also been demonstrated [57], although scale structure still needs to be confirmed for this population. A brief seven-item version has also been validated for screening use with HSDD in surgically menopausal women.

The most recently published measure for assessing women’s sexual function is the Monash female sexual satisfaction questionnaire (MFSSQ) and was developed specifically to assess acute therapeutic effects [58]. The 12-item measure was developed from 10 interviews with women, which led to domains of receptivity, arousal, lubrication, sexual pleasure, sexual satisfaction, and orgasm. The validation was conducted in pre- and postmenopausal women who were dissatisfied with their sexual function. The MFSSQ can be used to screen women dissatisfied with their sexual dysfunction, but cutoff scores for the separate domains have yet to be determined. Reliability of the orgasm and receptivity domains were not ideal and should be explored further. Responsiveness of the scale was not reported.

Disease-Specific Questionnaires for Use in Women with PFD

Sexual function measures should seek to evaluate the impact of PFD on sexual function and ultimately the subsequent impact of intervention. The few questions relating to sex in other quality-of-life questionnaires give a score of an overall impact on quality of life (KHQ, IIQ, electronic personal assessment questionnaire [ePAQ]) and are therefore less suitable to examine sexual impact in detail. General questionnaires will analyze function in general populations but may not be sensitive enough to detect subtle changes. Confounders such as age and menopausal status need to be accounted for and could alter the suitability of a particular instrument. For these reasons, disease-specific measures are the gold standard (Table 15.2).

There are two validated condition-specific sexual health measures for PFD available to date: PISQ and the International Consultation on Incontinence Questionnaire—Vaginal Symptoms (ICIQ-VS) [59]. Unfortunately, neither is validated in women with rectal symptoms. The PISQ is currently the most widely used. Both have undergone construct validity and reliability testing. The PISQ has been validated in more languages than the ICIQ-VS and therefore to date may be more suitable for international use.

The PISQ (31 items) has three domains: behavioral–emotive (frequency, orgasm, satisfaction), physical, and partner related (patient perception of). The TISQ has detected an improvement in sexual function in 70% of patients undergoing postsurgical repair of PFD, with an increase in physical and partner-related domains but no significant change in orgasm, desire, or arousal. Many studies using non-disease-specific tools have shown no change, which may be in part due to their lack of sensitivity or could really suggest limited change with surgery. The PISQ results correlate well with established general questionnaires including the FSFI and sexual history form function 12 [60]. It also differentiates depression associated with poor sexual function. Higher scores in the PISQ indicate better function. Normative scores with general population testing established a mean score of 94, maximum being 124. There is a short-form PISQ 12 [61] that correlates well with PISQ 31 scores. The normative score in PISQ 12 in the general population without prolapse or incontinence is 40, maximum score 48. The PISQ 12 scores can be multiplied by 2.58 to equal a PISQ 31 score. Increasing severity of PFD is generally associated with reduced PISQ scores. The PISQ however has its limitations. It cannot diagnose FSD at present, although as stated earlier, global normative values have been determined. It is not suitable for women in same sex relationships. As it excludes all women not engaging in penetrative intercourse and does not screen for other sexual activity, it may underestimate the impact of PFD. The International Urogynecology Association has developed a revision of the PISQ 31 to address issues considered important by an expert panel—the revised PISQ-IR [62].

Table 15.2 Factors to Be Considered When Choosing Sexual Function Assessment Questionnaires for Patients with Pelvic Floor Disorders

Patient factors	**Clinician factors**
Length/number of other questionnaires	Length/number of other questionnaires
Acceptability	Consistency
Validity/reliability	Validity/reliability
Simplicity	Reproducibility
Relevance	Captures outcomes of interest
Cultural validity	Generic/condition specific/disease specific
Language	Self/interviewer administered

The FSFI, a measure to assess FSD (see aforementioned for further details), has also been extensively used in urogynecological studies. One study investigating the effects of vaginal surgery on women with PFD concluded that domain scores changed but overall the scores did not improve [63]. The authors suggest one problem replaces another—altered vaginal anatomy before surgery to dyspareunia postsurgery. This demonstrates the possible unsuitability of general sexual functional scales for the PFD patient groups. Lack of any activity due to the disease process will not be assessed adequately. This has led to the use of the Sexual Distress Scale that measures distress due to the inhibition of sexual function and can be used to measure impact of the disease process on sexuality and benefit of intervention over time, without a need for engagement in sexual activity of any kind [64].

This may be particularly important for women with pain syndromes such as chronic bladder pain syndrome that disproportionately affects younger women and their sex lives. A study using the FSFI detected up to half of women with interstitial cystitis/painful bladder syndrome or recurrent urinary tract infections has a diagnosis of FSD with a deterioration in desire, lubrication, and satisfaction but no difference in arousal or orgasm [65]. Yet, a North American epidemiologically validated questionnaire did not find a significant association between PFD and sexual activity or satisfaction [66]). Overall, the use of nonvalidated and generic questionnaires makes urogynecological studies of sexual function difficult to compare and the results, if contradictory, are inconclusive. Therefore, when determining the right tool to be used, the outcomes of value should be carefully considered to ensure that these are adequately captured.

CLINICAL PRACTICE VS. CLINICAL TRIALS

Ascertaining which measure to use will be based on the setting and research questions under consideration. For instance, if the measure is to be used in clinical practice to monitor patient outcome, then a short instrument would be more realistic to mitigate the time burden for both clinician and patient (e.g., short-form CSFQ). If, however, the aim is to test a new therapeutic agent in a clinical trial, the most relevant measure regardless of length would be the best to ensure all aspects of FSD are captured in the most robust manner possible (e.g., FSFI, SFQ). Alternatively, a clinician may wish to use a measure to help screen for potential sexual function problems and needs a short measure that can also provide guidance on likelihood of FSD or even in relation to a particular FSD domain (e.g., SFQ). The use of a disease-specific tool validated in the appropriate population with a representative recall period (e.g., PISQ-IR) may be most useful to detect global change in sexual activity associated with therapeutic intervention, without the need for diagnosis of specific sexual dysfunctions. Regardless of setting, when choosing a measure, ensuring appropriate information of interest is obtained is essential. Then, an assessment of the measures validity and reliability in the population of interest to the clinician should be evident.

CONCLUSION

The tendency of women to become less interested in sex and men less able to perform with age may be distinguishable with well-designed instruments. It is important to evaluate the engagement in sexual activity and the reasons why it may have ceased or become less satisfying in women with PFD. The distress caused by these difficulties and its alleviation by urogynecological interventions are the information sought by clinicians and that should guide the management of patients. In the area of sexual function, the only reproducible and consistent method of reporting these outcomes is with well-designed, validated questionnaires.

16 Questionnaires to Assess Bowel Function

Said Mohamed, David Chatoor, and Andrew Williams

INTRODUCTION

Assessment of bowel function will undoubtedly require a thorough history and clinical examination. However, one needs a qualitative method of assessing not only the type but also the severity of the condition. This requirement is not only needed clinically but also as a research tool in order to compare different groups and monitor the outcome of interventions. As a result of this, questionnaires are widely used in clinical settings for this purpose.

A full appraisal of the use of such tools in the entirety of bowel disease is beyond the scope of this chapter, which will therefore focus on pelvic floor disorders—in particular, fecal incontinence and constipation/evacuatory disorders.

Questionnaire assessment of bowel function is a challenge due to the fact that normal bowel function varies widely not only within an individual but also between individuals. In addition, these ranges overlap between bowel disorders and pelvic floor disorders. As a result, questionnaires lack sensitivity and specificity for particular pelvic floor disorders.

There is the tendency to assess the pelvic floor in a segmental fashion (anterior, middle, and posterior compartments); however, the International Consultation on Incontinence (ICI) was convened in 1998 to develop a modular assessment of pelvic floor function using specific bowel, bladder, sexual, and prolapse assessment tools (www.iciq.net). In particular, emphasis was put on the need to develop tools that assess the severity and quality of life of those patients with incontinence. The committee justified the questionnaires as providing methods for the standardized collection of data from patients relating to incontinence and lower urinary tract symptoms [1]. In addition, the ICI defined principles that underpin the design of questionnaires. Empirical evidence is required to show that a questionnaire is measuring what it was supposed to do and is robust and repeatable (psychometric properties): having therefore validity, reliability, and responsiveness to change [2,3]. The ICI [4] recommended the following schema to assess the quality of questionnaires, and this will be adopted for this chapter:

Grade A—*Highly recommended*: Published evidence confirming robust validity, reliability and responsiveness. “Validity, reliability and responsiveness established with rigour.”

Grade B—*Recommended*: Published evidence confirming two out of the three dimensions (validity, reliability, and responsiveness) usually validity and reliability. “Validity and reliability established with rigour, or validity, reliability, and responsiveness indicated.”

Grade C—*With potential*: Early development—further work required and encouraged.

The ideal assessment tool for bowel dysfunction is yet to be developed. There has been a little guidance from the major gastroenterology or colorectal societies to suggest which bowel-specific questionnaires should be used both for research or clinical practice. This advice is difficult to give, however as there are no highly recommended tools to date with established reliability and validity that are “Grade A” for bowel specific or global pelvic floor function. It is clear that questionnaire assessment of urinary incontinence in particular is far more developed than equivalent tools for bowel-related pelvic floor disorders [5].

QUESTIONNAIRES TO ASSESS SYMPTOMS AND QUALITY OF LIFE IN PATIENTS WITH FECAL INCONTINENCE

The assessment of bowel function has gradually improved as the focus has changed from a physician outcome assessment to a patient-reported outcome. Parks in 1975 was one of the first to stratify fecal incontinence to assess clinical outcome and he divided this into four grades of severity based on the consistency of stool lost (continent, incontinence to flatus, incontinence to liquid, and incontinence to solid stool). He later used this to assess outcome of surgery, namely the postanal repair. It was later appreciated that it was not only the loss of stool that was important to record, but also how frequently this occurred. Subsequently, the frequency of incontinent episodes was included in the Wexner summative score. Events surrounding and leading up to the incontinent episode became added features, to include the degree of fecal urgency and pad usage in the further development by the St. Marks group.

Questionnaires initially focused on symptom severity; however, changes in symptom severity do not always correlate with a clinical change. The focus subsequently and appropriately has moved away from the severity of symptoms but on the impact of these symptoms on lifestyle, and so detailing this, quality of life tools have been introduced.

To date, the most commonly used questionnaires in clinical practice and clinical research are the "Wexner" incontinence score and the generic SF-36 quality of life questionnaire, which has set a precedent. This makes it difficult to introduce newer tools, as comparative studies such as systematic reviews and meta-analysis become more of a challenge to complete.

It is also important to note that the measurement of improvement very much depends upon the perspective of the assessor, i.e., it varies depending upon who is assessing the situation. There can be discordance between the physician and the patient's perspective. For example, the reduction in stool frequency and delay in urgency time can be more important to improve a patient's quality of life than the frequency of incontinence. Frequency of incontinence is, however, a more tangible measurement for a physician to measure. As such, there has been a growing trend toward patient-reported outcomes to reflect the subjective patient experience.

Questionnaires have become more complex over time, incurring some biases, for example, response fatigue. There needs to be a balance between clinical utility and complexity. So, there has been a trend to shorter and validated forms of impact assessment.

Fecal incontinence (FI) is a major healthcare issue that affects 2%–24% of the adult population [6]. The FI can be defined as the recurrent involuntary excretion of feces in inappropriate places or at inappropriate times. It can be either urge incontinence (inability to defer defecation) or passive incontinence (lack of awareness of the passage of feces, gas, or mucus via the anal canal) [7]. The etiology of FI is wide-ranging [8] and rectal evacuation is linked to pelvic floor function [9]. It is therefore necessary to consider assessment of both bowel function and control synchronously. Evacuatory dysfunction may result from a variety of underlying pathologies including outlet obstruction, slow transit or other mechanical, pharmacological, metabolic, endocrine, and neurogenic abnormalities [10].

A large number of questionnaires have been developed to identify the severity of FI and its influence on health-related quality of life (HRQL). Despite the large number, only a few are in regular use in research practice and fewer are used in clinical practice. The quality of psychometric evidence assessing these questionnaires varies widely and their recommendations are graded according to their evidence.

International Consultation on Incontinence Modular Questionnaire Bowel-(Still in Development) ICIQ-B

The ICIQ modular questionnaire remains the gold standard in questionnaire selection in clinical practice and in research [11,12]. It was developed by the ICI and has been robustly validated in relation to urinary incontinence. The ICIQ-B was specifically designed for fecal incontinence (www.iciq.net). This is a 21-point questionnaire that covers bowel pattern, bowel control, and quality of life. The four unscored items included to evaluate important issues from a clinical or patient perspective. Although studies are still ongoing, the ICIQ-B has been recently evaluated [13]. In this study, there was a good to very good reliability and reasonable response to changes in symptom and quality of life status following intervention. The authors concluded that the questionnaire is robust enough to be used in research and clinical practice. Further studies are awaited, but it is likely that this will achieve the highest level of recommendation.

Fecal Incontinence Quality of Life Scale (Grade B)

The Fecal Incontinence Quality of Life Scale developed and tested by Rockwood et al. [14]. It measures impact of anal incontinence over four scales of HRQL; lifestyle (10 items), coping/behavior (9 items), depression self-perception (7 items), and embarrassment (3 items). The purpose of the questionnaire is to measure the effect on quality of life of treatment for individuals with fecal incontinence. A panel of colorectal surgeons and researchers generated the items. 118 patients, and 72 controls took part in the study.

The questionnaire showed good discriminant validity, with significant differences between patients with fecal incontinence and those with other gastrointestinal disorders. Test–retest reliability at a mean interval of 8 days was satisfactory, with correlations for the 4 scales of 0.8–0.96. Internal consistency of the 4 scales was >0.7. Although there was responsiveness data, the questionnaire nevertheless offers a valid and reliable measure of the impact of fecal incontinence on quality of life in men and women with this condition.

Manchester Health Questionnaire Data (Grade B)

This is based on items adapted from the King's Health Questionnaire [15]. Structurally, they have the same features but use a slightly different format. The Manchester health questionnaire data uses a 5-point response scale (rather than the 4-point scale in the KHQ). Items from the HRQL as well as a symptom severity scale are included in the questionnaire. Face validity was assessed by interview with 15 patients with fecal incontinence. Test–retest reliability was measured (Pearson correlation >0.8 in all 9 domains).

The questionnaire was posted to 236 women with fecal incontinence, of which 159 returned completed questionnaires. 121 performed test–retest at a mean interval of 20 days. Cronbach's alpha was >0.7 in all domains tested, indicating adequate internal consistency.

Convergent validity was assessed by comparison with responses in the SF-36, which showed significant correlations between domains of the two instruments.

Birmingham Bowel and Urinary Symptoms Questionnaire (Grade B)

This questionnaire was developed to evaluate both bowel and urinary dysfunction in women. It consists of 22 items that were generated by a panel of experts following a review of the existing literature [16,17]. The questionnaire was evaluated in 141 asymptomatic women and 489 patients. Analysis of the data showed clinically relevant four-factor structure: constipation, evacuatory function anal incontinence, and urinary symptoms, with good distinction between patient groups suggesting good internal structure. Cronbach's alpha showed internal consistency and Kappa values showed good test-retest reliability. Therefore, the authors recommended the questionnaire to be used for both as a research tool and as a clinical measure.

Wexner Score (Grade C)

This is also called the Cleveland Clinic Incontinence Score and was developed in the Cleveland clinic in 1990. It was developed to objectively assess patients with incontinence in order to measure outcome following treatment [18]. It consists of tables for entry of clinical details and a grading system for the type of incontinence ranging from never to always. The scores are then added to generate a figure from 0 (fully continent) to 20 (severely incontinent). This is the most widely used severity index score in Europe and America and its psychometric credentials have been evaluated recently [19,20]. However, the ICI committee has not recommended a higher grade of recommendation due to the lack of more stringent validation.

St. Mark's Incontinence Score (Grade C)

This is a tool designed to assess the severity of fecal incontinence. It has only five questions that address fecal leakage, bowel urgency, the use of pads, medication, and interference with daily activities [21]. Initial validation involved comparing this tool with the Wexner score in a small group of patients [22]. The results were encouraging and showed good inter-instrument correlation and good relationship with a diary card and objective clinical impression. However, another large study of 390 patients that looked at patients with fecal incontinence and compared subjective visual analogue scale score to the St. Mark rescore showed only moderate correlation regardless of the severity of the incontinence [23]. This lack of robust validity leads the ICI panel to state that the tool had potential although more data are required before it can be fully recommended.

Pescatori Incontinence Score (Grade C)

This tool is hardly used in clinical practice. It was developed in 1992 and uses a number to letter system to the type of incontinence (letter A: flatus/mucus; letter B: liquid; letter C: solid; number 1: occasionally; number 2: weekly; number 3: daily) [22]. No comparison has been made with other tools.

Mayo Fecal Incontinence Survey (Grade C)

This is a tool that is used not only for the assessment of fecal incontinence but also its associated symptoms and the risk factors for developing the symptoms [24]. It is a 13-item questionnaire that has been extensively studied [25–27]. It has a good reliability and validity but very little data exist on responsiveness to clinical change.

Elderly Bowel Symptoms Questionnaire (Grade C)

This is another questionnaire developed by the Mayo Clinic group looking at the elderly with bowel symptoms [27]. It was a postal questionnaire with a 77% response rate and test–retest reliability was acceptable.

Fecal Incontinence and Constipation Assessment (Grade C)

This questionnaire is a modification of other existing tools that the Mayo Clinic developed [28]. It is a 98-item questionnaire that assesses the frequency and type of incontinence, number of pads used daily and the severity of urgency. It was validated in an outpatient clinic involving 83 patients. There were 20 of the patients retested 6 months later in order to assess the validity. Although the sample was small, the reproducibility was acceptable.

EQ-5D (Grade B)

This is a generic quality of life tool, applicable across many disease states, translated into most languages. The EQ-5D (developed by the EuroQol group with five dimensions), is a descriptive system that has five dimensions/questions related to mobility, self-care, usual activities, pain/discomfort, and anxiety/depression. In tandem with this addition, there is also a vertical visual analogue scale EQ-VAS, 20 cm (0–100) for self-rated health. It is an HRQL instrument, and one recommended by the National Institute for Health and Care Excellence particularly for the use of health economic analysis in calculations of quality-adjusted life-years (QUALYs). It has been featuring more in clinical trials for fecal incontinence. Its simplicity and ease of analysis is likely to see this gaining popularity over the more complex SF-36 [29].

QUESTIONNAIRES TO ASSESS SYMPTOMS AND QUALITY OF LIFE IN PATIENTS WITH CONSTIPATION/BOWEL EVACUATION DIFFICULTIES

Constipation is a problem that affects a significant proportion of the world's population and is responsible for symptoms and disorders that create discomfort and morbidity, with consequent high social and economic costs for health care systems. Constipation is a subjective symptom that can be related to a multitude of factors, including dietary, psychological, cultural, anatomic, and functional aspects. In addition, constipation is still surrounded by misconceptions and taboos that hamper an objective evaluation and encourage self-medication that is not always innocuous to the patient care.

The absence of firm criteria for the diagnosis of digestive functional disorders includes dietary, psychological, cultural, anatomic, and functional aspects. In addition, ecological and clinical research led a group of experts in the 1980s to create committees for establishing consensus on the criteria used to diagnose these problems [30]. These were known as the Rome criteria. In 1999, the criteria were modified on the basis of new knowledge gained, and they are now referred to as the Rome II criteria [31].

Rome II committee defined functional constipation as occurrence of two or more of the following symptoms for at least 12 weeks, which need not be consecutive, in the preceding 12 months and in the absence of structural and biochemical explanation: Straining during at least 25% of defecations, lumpy or hard stools in at least 25% of defecations, sensation of incomplete evacuation for at least 25% of defecations, sensation of anorectal obstruction/blockage for at least 25% of defecations, manual maneuvers to facilitate at least 25% of defecations (e.g., digital evacuation, support of the pelvic floor), fewer than three defecations per week.

The Rome II criteria for the diagnosis of chronic constipation differ from the Rome I criteria in that they incorporate two new symptoms to identify individuals with obstructed defecation: anal blockage and manual maneuvers to defecate. In addition, the new criteria exclude subjects presenting with loose stool episodes and irritable bowel syndrome. The Rome III criteria (2006) were an update on Rome II and it added the following to the existing criteria: (1) loose stools are rarely present without the use of laxatives and (2) there are insufficient criteria for irritable bowel syndrome. These criteria must be fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis [32].

Patient Assessment of Constipation Quality of Life (Grade B)

The PAC-QOL is a self-reported questionnaire that was used to measure the quality of life of patients [33]. The validated PAC-QOL is composed of 28 items grouped into four subscales: physical discomfort, psychosocial discomfort, worries and concerns, and satisfaction. The first three subscales are used to assess the patient dissatisfaction index, with an overall score ranging from 0 to 96 (where lower scores correspond to better quality of life). The satisfaction subscale includes four items with a global score ranging from 0 to 6, so that each patient's self-reported definitive outcome is defined as either poor [0–4], fairly good [5–8], good [9–12], or excellent [13–16]. This questionnaire has been validated in Europe, North America, and Australia [34]. It, however, focuses less on specific symptoms and their severity.

In order to address severity, some authors have developed it to be used with the symptom severity measure: the constipation symptom assessment instrument (PAC-SYM), another sister questionnaire which has 12 items under 3 subscales assessing: stool symptoms, rectal symptoms and abdominal symptoms [34]. It also has good internal consistency and retest reliability. It was also able to assess responders and nonresponders showing its response to change as discriminant validity.

Wexner Constipation Score (Grade C)

This is the most widely used scoring system in the assessment of constipation [30]. Its aim is to stratify the severity of constipation based on a set of subjective symptomatic complaints. There are eight questions in this score and a global scale of (0–30). Constipation is defined if the score is greater than 15. This score has been widely accepted because it has a good predictive validity but unfortunately does not address quality of life.

The Chinese Constipation Questionnaire (Grade C)

The Chinese Constipation Questionnaire [35] is a six-item self- report measure designed to diagnose functional constipation in Chinese participants. This scale consists of six items with four subscales: bowel function, stool rectal symptoms, laxative use, and abdominal symptoms. A composite score is generated by principal component analysis with a cut-off score of more than 5 being able to discriminate between controls and constipated patients with both a sensitivity and specificity of 91%. This scoring system is a simple validated tool more commonly used in oriental countries in outcome measures.

The Constipation Severity Instrument (Grade C)

Varma et al. [36] developed this tool that consists of 16 questions under 3 subscales: colonic inertia (slow transit), pain (irritable bowel syndrome C symptoms), and obstructive defecation. It has been validated using 191 patients with constipation symptoms and 103 controls. The instrument has good discriminatory validity and good convergent validity when compared with other established questionnaires. This instrument is quickly gaining use in both clinical and research settings, especially when patients present with subtypes of constipation syndromes.

Knowles Eccersley Scott Symptoms Score (Grade C)

The Knowles Eccersley Scott symptoms score is an 11-point tool for the diagnosis of constipation [37]. It has the added advantage of including various subtypes of constipation. However, no definition of constipation has been given and this makes the validity of the test very difficult to assess.

Gastrointestinal Quality of Life Index (Grade C)

The gastrointestinal quality of life (QoL) questionnaire [38] was designed to address all gastrointestinal symptoms and therefore is not specific for constipation. It includes 36 items with 5 possible answers, and it has a maximum possible score of 180.

Another statistically validated QoL questionnaire, the Constipation-Related Quality of Life [39], has been developed. This includes four domains: social impact (11 items), distress (11 items), usual diet (11 items), and defecation features (4 items). It appears to be an invaluable tool for assessing the effects of constipation on the quality of life.

Obstructive Defecation Syndrome Score (Grade C)

Obstructed defecation syndrome (ODS) is an emerging and challenging clinical problem described by normal desire to defecate with impaired ability to evacuate contents from the rectum. This new entity has been a subject of debate with gastroenterologists and colorectal surgeons during the last few years. The mainstay of treatment for this condition is conservative, with measures involving dietary manipulation and biofeedback techniques using different modalities. Surgical interventions such as Rectopexy and Stapled Transanal Rectal Resection (STARR) are reserved for those who fail on the above measures.

A new scoring system was developed by Longo et al., who also devised the STARR procedure for the treatment of ODS to correlate the symptoms with objective physiological findings and to allow uniformity in assessment of its severity [40–42]. The original Longo score (0–40) is an 8-point scale (defecation frequency, straining, sensation of incomplete evacuation, recto/perineal pain/discomfort, activity reduction per week, laxatives, enemas, and digitations). A modified Longo score is now in use [42] and a lifestyle change parameter has been added to the seven symptom-based parameters. Currently, Modified ODS Longo score is the most commonly used scoring system to decide treatment strategy for ODS patients as well as an outcome measure. It has no quality of life items and is still to be validated.

Measure Yourself Medical Outcome Profile (Grade C)

This is a bespoke questionnaire and is evolving as one of the evolving self-reported tools with potential clinical impact. Patients are asked for their top two troublesome symptoms and the impact of these on their activities of daily living and on general well-being, with both being scored using a 7-point [43] Likert scale. It is simple to use and will apply to all bowel disorders. As it involves generic questions, it allows the patient to self-report symptoms that are important to them. These types of self-reported scoring systems are particularly useful in the follow up assessment of patients and are more sensitive to change than the SF-36. This questionnaire is individualized, thus making it difficult to compare different patients, thus making it less of a research tool, and more of a clinical tool for individual outcome.

CONCLUSION

A wide range of questionnaires and scoring systems are in existence in order to evaluate bowel function. The mere fact of the bewildering array of different tools is an indication of the generally low quality of the tools. Very few of the questionnaires have been rigorously assessed despite their widespread use. Organizations such as the ICI and the Rome Criteria have recognized this problem and one hopes that in the future international consensus will be achieved in order to improve the quality of the tools that are available to assess bowel function currently.

17 International Consultation on Incontinence Modular Questionnaire

Nikki Cotterill and Paul Abrams

WHAT IS ICIQ?

The first International Consultation on Incontinence was held in 1998 to provide evidence-based recommendations regarding all aspects of incontinence care and research. Committees of experts were convened to encompass all the relevant subject areas. These individuals were from multidisciplinary backgrounds and represented the worldwide scientific community and the range of specialities involved. Each committee was tasked with performing a systematic review of the relevant medical literature in order to make recommendations for clinical practice and research. One such committee responsible for the review of symptom and quality of life assessment identified numerous published questionnaires for the assessment of urinary incontinence (UI). Grades of recommendation regarding their use were applied based on their degree of validation in the published literature [1]. The use of questionnaires with the highest levels of validation was encouraged in clinical practice and research to enable robust evaluation of symptoms and their impact on quality of life and to facilitate the comparison of results across studies. It was also suggested that there was a need for a universally applicable, brief, and simple UI questionnaire to be developed and used widely across the population in clinical practice and research—the International Consultation on Incontinence Modular Questionnaire (ICIQ)-UI Short Form [2]. Such an instrument would facilitate comparisons between findings in different settings and studies and was supported by the ICI Scientific Committee [3].

An advisory board was convened to steer development of this questionnaire, and while not included in the review at the first consultation, the lack of questionnaires available for bowel symptoms and incontinence, and vaginal symptoms such as prolapse, was recognized. The decision was taken to expand the project to enable the recommendation and development of, where required, high-quality, fully validated questionnaires for all lower pelvic dysfunction related to incontinence. The ICIQ project was then established to include a wider spectrum of urinary, bowel, and vaginal symptoms and their impact on quality of life.

AIMS AND OBJECTIVES

The ICIQ's objectives are to provide consensus on the use of published questionnaires for the assessment of lower pelvic symptoms and their impact on quality of life. Three aims underpin the ICIQ in order to achieve clarity over questionnaire use:

1. To recommend high-quality self-completion questionnaires according to evidence of validation
2. To promote wider use of questionnaires to standardize assessment of lower pelvic dysfunction and its impact on quality of life
3. To facilitate communication in different patient settings and different patient groups

HOW IS THE ICIQ DEVELOPED?

Development of the ICIQ is achieved in two ways:

1. Inclusion of existing high-quality questionnaires with the author's permission
2. Production of new questionnaires

Inclusion into the ICIQ is based on a principal factor: evidence of a questionnaire's robust validation. Psychometric testing of questionnaires for use in clinical practice and research is considered essential to afford confidence in the results obtained [4]. This is of particular importance where decisions regarding treatment or research outcomes are made. There are three main components to standard psychometric evaluation:

1. Validity—indicates that the instrument is a valid measure of the concept in question
2. Reliability—indicates that the instrument can measure the concept in a reproducible and consistent manner
3. Sensitivity to change—indicates that the instrument is able to detect real change in the concept under evaluation [4–9]

To achieve these standards requires considerable time and effort. Production of a new questionnaire therefore is only undertaken when there is a specific requirement for the new instrument and when available instruments are inadequate.

METHODS OF ICIQ DEVELOPMENT

ICIQ questionnaire production follows a standard protocol incorporating mixed methodology.

Qualitative studies are undertaken to achieve the aims of both patients and clinical relevance dependent on the nature of the questionnaire. Potential respondents, symptomatic patients, for example, are particularly well placed to provide insight regarding the lived experience of their symptoms and describe the impact on their quality of life [10]. Issues required for clinical evaluation may be more readily identified by clinical experts particularly where specific clinical manifestations are required to infer diagnosis, for example, urinary urgency and frequency are symptoms characteristic of overactive bladder (OAB) [11]. There is inevitably overlap between these groups however. This process ensures that the most pertinent issues for evaluation are identified. The value of conducting qualitative enquiry is also in establishing the most appropriate phraseology and terminology for self-report questionnaires [12]. This approach is considered essential in producing a credible patient-reported tool [13] and provides a sound evidence base for questionnaires to go on and be evaluated using rigorous quantitative methods.

Parallel studies are conducted to evaluate different aspects of validity, reliability, and sensitivity to change in subgroups of potential respondents (e.g., outcome following conservative and surgical treatments). These substudies provide larger datasets on which to conduct numerous statistical analyses in order to make decisions regarding the most robust measurement question items to retain in the final version of the questionnaire. Further consultations with clinicians and potential respondents are conducted to ensure the final version of the questionnaire reflects clinical and patient relevance while displaying the most robust psychometric properties.

The ICIQ’s international nature requires that translations are available, which is also conducted according to an established protocol involving structured translation and back translation to ensure the original meaning of the questionnaire is retained. Over 40 language versions are now provided across available ICIQ modules.

HOW TO USE THE ICIQ

Sixteen ICIQ modules/questionnaires are currently available for use, which includes two recently finalized tools—the ICIQ-Bladder Diary and ICIQ-LTCqol for the evaluation of quality of life associated with long-term catheterization (discussed in detail in the following texts). Clinicians or researchers are able to select modules to compile a tailored questionnaire set that meets their study/clinical practice requirements to achieve complete evaluation.

In order to simplify this, modules have been categorized to aid selection (Table 17.1).

The ICIQ recommends the use of a “core” or “symptom-specific” module and an “add-on” quality of life measure in all patient evaluations for both clinical practice and research. Symptom alleviation may not indicate a difference in impact on quality of life and so the evaluation of both is recommended to encompass all relevant aspects to the individual [14,15]. This approach can also target treatment to the most bothersome component of a symptom complex. The features of each module are summarized in the following texts to inform decisions regarding questionnaire selection.

Table 17.1 International Consultation on Incontinence Modular Questionnaire Modular Structure

			Recommended Add-on Modules			
Condition	Recommended Modules	Optional Modules	QoL	Generic QoL	Sexual Matters	Posttreatment
A. *Core modules*						
Urinary symptoms	Males: ICIQ-MLUTS Females: ICIQ-FLUTS ICIQ-Bladder Diary	Males: ICIQ-MLUTS LF Females: ICIQ-FLUTS LF	ICIQ-LUTSqol	SF-12	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	ICIQ-satisfaction[a]
Vaginal symptoms and sexual matters	ICIQ-VS		ICIQ-VSqol[a]	SF-12		
Bowel symptoms	ICIQ-B		ICIQ-BSqol[a]	SF-12		
Urinary incontinence (UI)	ICIQ-UI Short Form	ICIQ-UI LF[a]	ICIQ-LUTSqol	SF-12	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
B. *Specific patient groups*						
Nocturia	ICIQ-N		ICIQ-Nqol	SF-12	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
Overactive bladder (OAB)	ICIQ-OAB		ICIQ-OABqol	SF-12	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
Neurogenic	ICIQ-spinal cord disease[a]					
Long-term catheter users	ICIQ-LTC		ICIQ-CLUTSqol[a]			
Children	ICIQ-CLUTS[a]					

[a] In development

Recommended Modules

Core Modules

The questionnaire modules provide assessment of core symptoms of lower pelvic dysfunction:

- Lower urinary tract symptoms (LUTSs) (male and female specific versions): ICIQ-MLUTS/ICIQ-FLUTS
- Diary of urinary events: ICIQ-Bladder Diary
- Vaginal symptoms (female version only): ICIQ-VS
- Bowel symptoms focusing on anal incontinence (male and female applicable version): ICIQ-B
- UI (male and female applicable version): ICIQ-UI Short Form

Each questionnaire provides a comprehensive yet brief instrument for measurement of the stated symptoms and associated “bother.” The bother items attached to individual symptoms enable the individual to indicate areas causing the most impact on quality of life, as perceived by them. This can be a more sensitive indicator of treatment outcome than frequency of symptoms alone (Figure 17.1).

The bladder diary provides the first validated diary for the collection of bladder-related events. Qualitative studies were conducted to derive the parameters for inclusion followed by quantitative studies to evaluate the robustness of the tool.

The characteristics of the core ICIQ modules are summarized in Table 17.2.

Specific Patient Groups

This group of questionnaires provides assessment of some specific conditions or symptom complexes such as nocturia and OAB. This category also includes specific patient groups (e.g., children, individuals with long-term catheters). These instruments contain only question items associated with the symptom complex or have been developed specifically for use in a specific group. These questionnaires therefore are only utilizable in the stated populations and would need further evaluation for use in other groups:

- Nocturia (male and female applicable version): ICIQ-N
- OAB (male and female applicable version): ICIQ-OAB
- Patients with spinal cord disease: ICIQ-spinal cord disease
- Patients using long-term catheters: ICIQ-LTCqol
- LUTSs in children: ICIQ-CLUTS

Bother items are included for all except the children's questionnaire.

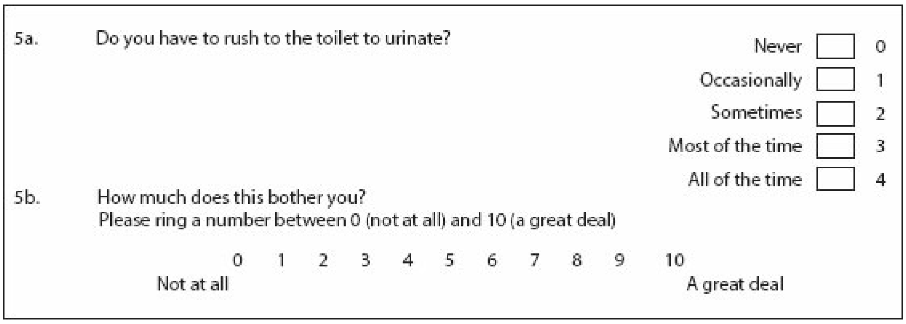
The characteristics and developmental progress of the ICIQ modules for use in specific patient groups are summarized in Tables 17.3 and 17.4.

Recommended Add-On Modules

Core Modules

This group of questionnaires incorporates quality of life and sexual matters modules. They are recommended to be completed as stand-alone questionnaires or alongside core or specific symptom evaluations. The core symptom modules described earlier contain bother items indicating impact on quality of life directly related to symptoms. Quality of life questionnaires cover more specific issues that are a consequence of symptoms (e.g., limiting activities and affecting relationships). The combination of symptom assessment with associated bother and a quality of life assessment provides a more complete evaluation of the patient's experience [15,22]. In addition, given the nature of lower pelvic dysfunction, sexual matters can also be affected and questionnaires are available for this further evaluation where appropriate:

- Quality of life associated with LUTSs (male and female applicable version): ICIQ-LUTSqol.
- Quality of life associated with vaginal symptoms (female version only): ICIQ-VSqol.
- Quality of life associated with bowel symptoms (male and female applicable version): ICIQ-BSqol.
- Sexual matters associated with LUTSs (male and female specific versions): ICIQ-MLUTSsex/ICIQ-FLUTSsex.
- Sexual matters associated with vaginal symptoms are included in the symptom questionnaire (ICIQ-VS) as the issues were considered too intrinsically linked to separate for evaluation.
- Sexual matters associated with bowel symptoms are included in the symptom and quality of life questionnaire (ICIQ-B) as the issues were considered too intrinsically linked to separate for evaluation.



5a. Do you have to rush to the toilet to urinate?

Figure 17.1 Example of an International Consultation on Incontinence Modular Questionnaire question item.

Table 17.2 Core Modules Available for Use

1. ICIQ-MLUTS	
Purpose	Comprehensive assessment of male lower urinary tract symptoms and associated bother
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [16,17]
Domains/items	Voiding

	Incontinence Individual items evaluating frequency and nocturia
Number of items	13
Available translations	26
Scoring system	0–20 voiding symptoms subscale 0–24 incontinence symptoms subscale Bother scales are not incorporated in the overall score but indicate impact of individual symptoms for the patient
Derived from	ICS*male*SF [16]
2. ICIQ-FLUTS	
Purpose	Comprehensive assessment of female lower urinary tract symptoms and associated bother
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [18]
Domains/items	Filling Voiding Incontinence
Number of items	12
Available translations	19
Scoring system	0–15 filling symptoms subscale 0–12 voiding symptoms subscale 0–20 incontinence symptoms subscale Bother scales are not incorporated in the overall score but indicate impact of individual symptoms for the patient
Derived from	Bristol Female Lower Urinary Tract Symptoms Questionnaire-Short Form (BFLUTS-SF) [18]
3. ICIQ-Bladder Diary	
Purpose	Comprehensive tool to enable robust recording of bladder-related events
Availability	Available for use Published evidence of validity and reliability, sensitivity to change implied but requires more extensive evaluation
Items	Fluid intake, urine output, bladder sensation, incontinence events
Duration	24 hour recordings for 3 days
Available translations	Initial translations in progress
Derived from	Newly developed module [19,20]
4. ICIQ-VS	
Purpose	Comprehensive assessment of vaginal symptoms and associated bother
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [21]
Domains/items	Vaginal symptoms Sexual matters Quality of life
Number of items	14
Available translations	2
Scoring system	0–53 vaginal symptoms subscale 0–58 sexual matters subscale 0–10 overall impact on quality of life subscale Bother scales are not incorporated in the overall score but indicate impact of individual symptoms for the patient
Derived from	Newly developed module
5. ICIQ-B	
Purpose	Comprehensive assessment of male/female bowel symptoms, predominantly anal incontinence, and associated impact on quality of life

Availability	Available for use Evidence to suggest validity, reliability, and sensitivity to change awaiting publication
Domains/items	Bowel pattern Bowel control Quality of life
Number of items	21
Available translations	2 in production
Scoring system	1–21 bowel pattern subscale 0–28 bowel control subscale 0–26 impact on quality of life subscale Bother scales are not incorporated in the overall score but indicate impact of individual symptoms for the patient
Derived from	Newly developed module
6. ICIQ-UI Short Form	
Purpose	Comprehensive assessment of male/female UI
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [2].
Domains/items	UI including items on frequency and amount of leakage along with overall interference A self-diagnostic item invites respondents to indicate the cause of incontinence
Number of items	4
Available translations	32
Scoring system	0–21 UI score Self-diagnostic item not scored
Derived from	Newly developed module

Bother associated with impact items is included as this can be very personal and quite unrelated to the frequency of the issue alone.

The characteristics and developmental progress of the ICIQ recommended add-on modules for use alongside the core questionnaires are summarized in Tables 17.5 and 17.6.

Specific Patient Groups

In the same manner as the symptom modules, quality of life modules are available for specific symptom complexes.

- Quality of life associated with nocturia (male and female applicable version): ICIQ-Nqol.
- Quality of life associated with OAB (male and female applicable version): ICIQ-OABqol.

The characteristics of the ICIQ recommended add-on modules for use in specific patient groups are summarized in Table 17.7.

Table 17.3 Specific Patient Group Modules Available for Use

1. ICIQ-N	
Purpose	Comprehensive assessment of symptoms of nocturia and associated bother
Availability	Available for use Evidence of validity, reliability, and sensitivity to change [16–18]
Domains/items	Frequency Nocturia
Number of items	2
Available translations	30
Scoring system	0–8 total score of both items Bother scales are not incorporated in the overall score but indicate impact of individual symptoms for the patient

Derived from	ICS*male*SF/BFLUTS-SF [16,18]
2. ICIQ-OAB	
Purpose	Comprehensive assessment of symptoms of OAB and associated bother
Availability	Available for use Evidence of validity, reliability, and sensitivity to change [16–18]
Domains/items	Frequency Nocturia Urgency Urge incontinence
Number of items	4
Available translations	22
Scoring system	0–16 total score of all items Bother scales are not incorporated in the overall score but indicate impact of individual symptoms for the patient
Derived from	ICS*male*SF/BFLUTS-SF [16,18]
3. ICIQ-LTCqol	
Purpose	Assessment of urinary symptoms and impact on quality of life associated with long-term urethral catheterization and related bother
Availability	Available for use Evidence of validity and reliability. Requires evaluation of sensitivity to change
Domains/items	Catheter function and concern Lifestyle impact
Number of items	17
Available translations	Nil
Scoring system	0–42 catheter function and concern subscale 3–15 lifestyle impact subscale
Derived from	Newly developed module (submitted for publication)

Table 17.4 Specific Patient Group Modules in Development

1. ICIQ-Spinal Cord Disease	
Purpose	Assessment of urinary symptoms and impact on quality of life associated with specific management devices and related bother
Current status	Draft instrument prepared Content validity testing and full psychometric validation to be commenced
Development methodology	Items generated by clinical experts and patients managing urinary symptoms with varying devices
Domains/items	Bladder function Issues associated with specific management devices Sexual matters Quality of life
Derived from	Newly developed module
2. ICIQ-CLUTS	
Purpose	Assessment of urinary symptoms in children
Current status	Draft instrument prepared and has undergone content validity testing Further validity testing underway in the United Kingdom, Italy, and Germany Reliability and sensitivity to change evaluation to be commenced
Development methodology	Items generated by clinical experts Criterion validity evaluated by comparison with gold standard clinical parameters
Domains/items	Urinary symptoms and incontinence
Derived from	Newly developed module

Optional Modules

This category includes lengthier questionnaires for more exploratory evaluation of the core symptoms of lower pelvic dysfunction. While these questionnaires are suitable for use in clinical practice, they have not been shortened for clinical efficiency and are therefore more widely used in research studies where exploration of a broader range of symptoms may be desired and more feasible:

- ICIQ-MLUTS Long Form/ICIQ-FLUTS Long Form
- ICIQ-UI Long Form

The characteristics of the ICIQ optional modules, availability for use and progress of one module in development are summarized in Tables 17.8 and 17.9.

Posttreatment Module

The issue of posttreatment satisfaction evaluation is being explored from various perspectives. To date, a fully validated questionnaire for generic use among individuals undergoing varied treatments for all lower pelvic dysfunction has not been fully validated. The feasibility of an ICIQ module for this purpose is undergoing exploration to establish if satisfaction following treatment can be characterized by a set of common question items applicable to all treatments. An alternative suggestion is that satisfaction may be simply assumed by alleviation of symptoms or improvement in quality of life. Ongoing studies will provide further evidence on which to make suggestions regarding posttreatment evaluation.

Table 17.5 Add-On Modules Available for Use

1. ICIQ-LUTSqol	
Purpose	Detailed assessment of quality of life issues associated with urinary symptoms and related bother
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [23].
Domains/items	Life restrictions Emotional aspects Preventive measures
Number of items	22
Available translations	45
Scoring system	0–76 total score of all items 0–10 overall impact on everyday life subscale Bother scales are not incorporated in the overall score but indicate impact of individual quality of life aspects for the patient
Derived from	King's Health Questionnaire [23]
2. ICIQ-MLUTSsex	
Purpose	Assessment of male sexual matters associated with urinary symptoms and related bother
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [17,24]
Domains/items	Erection and ejaculation issues Overall interference
Number of items	4
Available translations	24
Scoring system	0–12 total score of all items 0–10 overall impact on sexual matters subscale Bother scales are not incorporated in the overall score but indicate impact of individual symptoms for the patient
Derived from	ICS*male*SF [16,17,24]
3. ICIQ-FLUTSsex	

Purpose	Assessment of female sexual matters associated with urinary symptoms and related bother
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [25]
Domains/items	Pain and leakage with sexual intercourse Overall interference
Number of items	4
Available translations	18
Scoring system	0–14 total score of all items Bother scales are not incorporated in the overall score but indicate impact of individual symptoms for the patient
Derived from	BFLUTS [25]

Table 17.6 Add-On Modules in Development

1. ICIQ-VSqol	
Purpose	Detailed assessment of quality of life issues associated with vaginal symptoms and related bother
Current status	Draft instrument prepared and has undergone content validity testing Data collection ongoing
Development methodology	Items generated by clinical experts and patients with vaginal symptoms Content validity testing with potential respondents and clinical experts Multicenter postal administration to potential respondents for validity, reliability, and sensitivity to change data collection
Domain/items	Life restrictions Emotional aspects
Derived from	Newly developed module
2. ICIQ-BSqol	
Purpose	Detailed assessment of quality of life issues associated with bowel symptoms and related bother
Current status	Data collection complete and final analysis underway Evidence to suggest validity, reliability, and sensitivity to change
Development methodology	Items generated by clinical experts and patients with anal incontinence [12] Extensive content validity testing with potential respondents and clinical experts Multicenter postal administration to potential respondents for validity, reliability, and sensitivity to change data collection
Domains/items	Life restrictions Emotional aspects Preventative measures/coping strategies
Derived from	Newly developed module

Adaptation of the ICIQ

Studies have been conducted to evaluate the acceptability and equivalence of the psychometric robustness of electronic versions of the ICIQ. Qualitative studies were undertaken to evaluate the acceptability to the population of interest and to identify modifications required to enable the ICIQ to be completed in an electronic format. Quantitative studies were also undertaken to evaluate the comparability of findings between the different formats to ensure at least equivalence of the measurement properties, which is considered standard methodology for the conversion of paper questionnaires for electronic completion [28]. This will increase the versatility of the ICIQ at a time where technology is advancing at a pace.

Table 17.7 Specific Patient Group Add-On Modules Available for Use

1. ICIQ-Nqol	
Purpose	Detailed assessment of quality of life issues associated with nocturia
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [26]
Domain/items	Issues associated with sleep disturbance

	Preventive measures
Number of items	13
Available translations	27
Scoring system	0–48 total score of all items or 0–24 sleep/energy subscale 0–24 bother/concern subscale 0–10 overall interference caused by nocturia subscale
Derived from	N-QoL [26]
2. ICIQ-OABqol	
Purpose	Detailed assessment of quality of life issues associated with OAB
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [27]
Domains/items	Life restrictions Emotional aspects Measure to accommodate OAB
Number of items	26
Available translations	33
Scoring system	0–150 total score of all items 0–10 overall impact on everyday life subscale
Derived from	OAB-q [27]

Table 17.8 Optional Modules Available for Use

1. ICIQ-MLUTS Long Form	
Purpose	Detailed assessment of male lower urinary tract symptoms and associated bother
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [16,24]
Domains/items	Varied lower urinary tract symptoms
Number of items	23 (including the 13 items within the ICIQ-MLUTS)
Available translations	29
Scoring system	1–84 total score of all items Bother scales are not incorporated in the overall score but indicate impact of individual symptoms for the patient
Derived from	ICS*male* [17,24]
2. ICIQ-FLUTS Long Form	
Purpose	Detailed assessment of female lower urinary tract symptoms and associated bother
Availability	Available for use Published evidence of validity, reliability, and sensitivity to change [18,25]
Domains/items	Varied lower urinary tract symptoms
Number of items	18 (including the 12 items within the ICIQ-FLUTS)
Available translations	7
Scoring system	0–69 total score of all items Bother scales are not incorporated in the overall score but indicate impact of individual symptoms for the patient
Derived from	BFLUTS [25]

Table 17.9 Optional Module in Development

ICIQ-UI Long Form	
Purpose	Detailed assessment of perceived causes of UI
Current status	Draft instrument prepared and has undergone content validity testing Data collection ongoing
Development methodology	Items generated by clinical experts and patients with UI Extensive content validity testing with potential respondents and clinical experts

	Postal administration to potential respondents for validity, reliability and sensitivity to change data collection
Domains/items	For each perceived cause of incontinence (for example, physical activity), the frequency, amount, and degree of bother are evaluated
Derived from	Newly developed module

UPTAKE OF THE ICIQ

Use of the ICIQ in clinical practice and research has been encouraging in achieving the aims of standardized, high-quality assessment for symptoms of lower pelvic dysfunction and their impact on quality of life. More than 1200 requests for use of the various modules have been recorded and over 200 related publications have been identified. The most widely applied module is the ICIQ-UI Short Form (ICIQ), which is closely followed by the ICIQ-FLUTS reflecting the fact that most applications relate to the evaluation of female urinary symptoms. The ICIQ has most commonly been applied to clinical and general practice settings, alongside its considerable uptake in the research setting.

CONCLUSION

The ICIQ modular questionnaire project provides an expanding series of standardized questionnaires for the assessment of lower pelvic dysfunction and its impact on quality of life. The ICIQ provides clarity over which questionnaires to use by recommending only those with evidence of high quality and robust psychometric validation data. This assurance provides the user with confidence in the results obtained. This is particularly important in clinical practice and research where treatment decisions or trial outcomes increasingly rely on this source of evidence. Increasing awareness of the ICIQ aims to promote increased usage of standardized questionnaires thereby facilitating communication and more widespread comparisons between different treatments and in different patient groups worldwide.

18 Electronic Personal Assessment Questionnaire Pelvic Floor

Stephen Radley and Deepa Gopinath

BACKGROUND

Interest in questionnaire use in healthcare has largely been driven by the need for reliable and valid instruments for outcomes research. More recently, however, their use has now become a desirable, if not essential element in routine clinical practice [1]. This chapter explores the concept, development, and introduction of electronic assessment in urogynecology, aiming to bridge the divide between research use and day-to-day patient care.

Whereas electronic systems now provide integral elements in industries such as retail, finance, travel and communication; healthcare generally lags behind. Large-scale capital projects such as the National Health Service (NHS) National Programme for IT (now *Connecting for Health*) have proven to be long, complex, and expensive [2]. Paper-based recording systems are however increasingly recognized as being outdated, and change in this sector is gathering pace.

There is a growing enthusiasm for reducing the resource burden of questionnaire-based assessments using IT. Electronic data collection compares favorably with paper-based systems in terms of reliability and validity, with lower levels of missing data. Patients have found them relatively easy and even enjoyable to complete, offering efficiency advantages for large surveys [3,4]. When collecting sensitive data, computer-assisted interviewing results in greater openness and disclosure than paper-based questionnaires or face-to-face interviews [5–7]. These findings have implications for questionnaire use in urogynecology, both in research and clinical practice. Web-based and paper versions of the Pelvic Floor Distress Inventory-20 (PFDI-20), Pelvic Floor Impact Questionnaire-7 (PFIQ-7), and Pelvic Organ Prolapse/Urinary Incontinence Sexual Function Questionnaire (PISQ-12) have been compared and found to be reliable and with high correlations between the different formats [8,9]. The sample sizes in these studies were relatively small (n = 52), and although correlations were strong, differences were observed between different formats and not all patients were willing or able to use the electronic questionnaire. In the select sample of those who did use both formats, the majority expressed a preference for web-based completion.

PELVIC FLOOR QUESTIONNAIRES

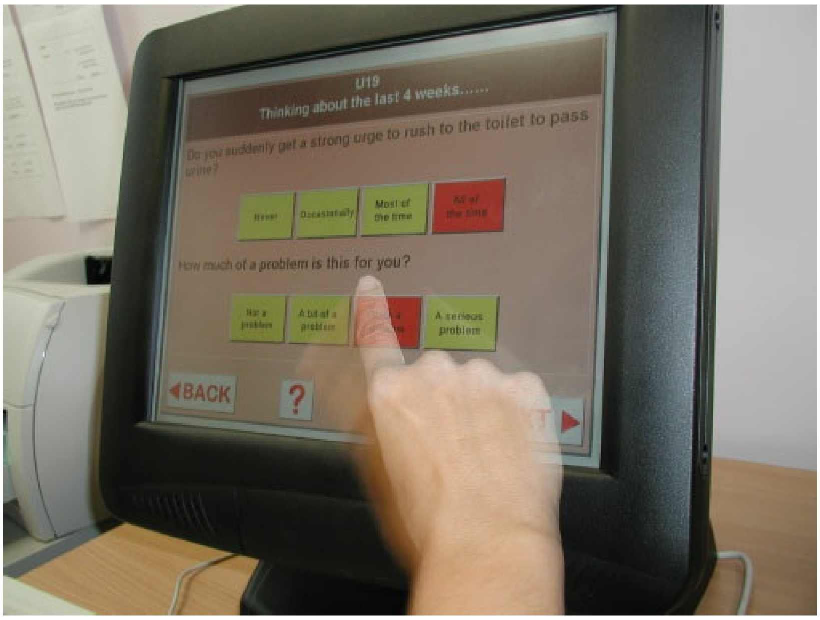
A range of questionnaires have been developed to measure and record symptomatology, conditions, health, and health-related quality of life in urogynecology. Such instruments have often been designed for a specific purpose or setting, the better established patient-reported outcome measures (PROMs) having been developed for research. Using questionnaires in direct clinical care presents substantially different challenges [10]. In order for a questionnaire to be clinically useful, it must be accessible, meaningful, and easy-to-use (both for patients *and* clinicians) as well as possessing demonstrable reliability, validity, and responsiveness. In order to inform clinical assessment, a questionnaire should ideally be completed *prior to* clinical consultation, although most condition-specific questionnaires are too narrow in their scope to be used in this way. Women with pelvic floor disorders commonly have interrelated problems, for example, bowel *and* urinary incontinence, incontinence prolapse, and prolapse *and* sexual dysfunction. This has driven the development of more generic urogynecology/pelvic floor questionnaires, covering a range of disorders. For these broader instruments, there is then a tension between the burden of providing sufficient detail and the lack of depth afforded by brevity.

DEVELOPMENT OF ELECTRONIC PERSONAL ASSESSMENT QUESTIONNAIRE: PELVIC FLOOR

The original concept for electronic Personal Assessment Questionnaire (ePAQ) arose from a desire to harness the accuracy and reliability of well-designed questionnaires in clinical practice, enhance communication, and provide in-depth, objective understanding of the patients' conditions. The aim was to utilize computer technology to provide an efficient, interactive, single instrument, addressing issues of feasibility faced with the use of paper questionnaires such as compliance, burden, and cost associated with entering, processing, and storing large volumes of clinical data (Figure 18.1) [11].

ePAQ was initially created as a web-based software application, using Microsoft Access® combined with Structured Query Language (SQL) server and dot Net programming to produce an interactive system for use on touch-screen computer terminals. The purpose-built Microsoft Access® "Q-Builder" software incorporated all the technical elements: physical layout and display (e.g., colors, buttons, and font sizes), item content, and response data. Active Server Pages provide dynamic and interactive elements, supporting a database interface with via SQL server that allowed data management on a single database. The system is forward-compatible with electronic data management software systems, allowing integration with other modalities such as new electronic results reporting and electronic patient records.

The initial prototype for electronic Personal Assessment Questionnaire: Pelvic Floor (ePAQ-PF) was based on existing paper-based questionnaires; Birmingham Bowel and Urinary Symptoms and Sheffield prolapse symptoms questionnaires were adapted and combined in a single instrument. Consultation with specialists in urology, gynecology, colorectal surgery, and sexual medicine identified additional items, whose format was unified to achieve consistency throughout. Subquestions on impact (as used in the ICS-Male and Bristol Female Lower Urinary Tract Symptoms Questionnaires) were included. Paper and electronic versions were reviewed by the local maternity user group who provided critical structured feedback. Psychometric testing was carried out in 432 patients in primary and secondary care [12]. Test–retest indicated good stability over time and patient acceptability was high. This was evaluated in terms of value and burden using a 10-item questionnaire (QQ-10), specifically designed for this purpose, and administered to patients immediately following their clinical episode [13]. ePAQ showed high value and low burden; most women find it relevant, valuable, and easy-to-use. Secondary factor analysis was carried out in a further 247 patients, confirmed the item content and 19-domain structure of the instrument now in clinical use, which was subsequently found to be responsive to change in women undergoing surgical intervention for incontinence and prolapse [14,15].



U19

Thinking about the last 4 weeks......

Do you suddenly get a strong urge to rush to the toilet to pass urine?

How much of a problem is this for you?

Figure 18.1 Touch-screen PC used in gynecology outpatient department. ePAQ was initially deployed in outpatient clinics using touch-screen terminals. The majority of patients now complete the questionnaire via the Internet. Women who are unable to complete online are invited to attend early in order to do complete the questionnaire using a touch-screen terminal, prior to their clinical consultation. This takes approximately 20 minutes.

QUESTIONNAIRE STRUCTURE AND CONTENT

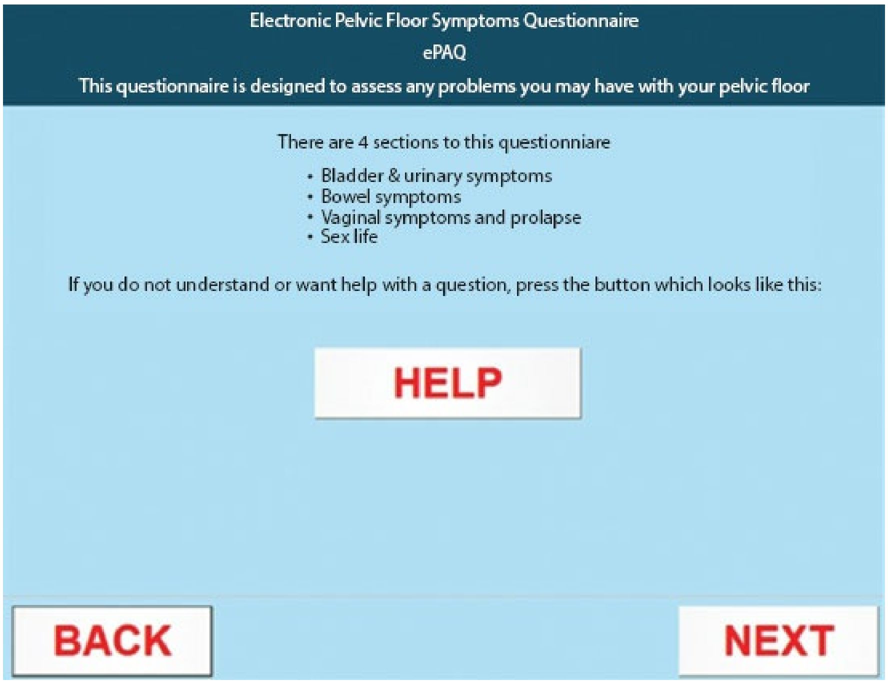
The main questionnaire section of ePAQ is preceded by introductory pages, which provide information about the system and instructions for unsupervised completion. The standard format presents one question per page, each of which includes its own “Help Page.”

Navigation through the questionnaire uses “Next” and “Back” buttons, with a “Skip” button allowing subjects not to answer a question, thereby eliminating accidental nonresponse—a fundamental problem with paper-based instruments (Figures 18.2 and 18.3).

The questionnaire automatically adapts responses to screening questions enabling skipping of nonrelevant items or sections, while more probing questions are presented when appropriate. Responses to key screening questions determine whether or not subsequent items are skipped, thereby minimizing burden (Figure 18.4). When subjects are asymptomatic, the number of questions is reduced, minimizing respondent burden. Conversely, symptomatic individuals undergo more detailed and relevant assessment.

The full questionnaire comprises 129 items, distributed across 4 dimensions: (1) urinary, (2) bowel, (3) vaginal, and (4) sexual (Figure 18.5). Within each dimension are four to five scored domains (19 in total), each comprising of three to seven items (questions). All items included in these domains are scored between 0 and 3. Domains themselves are scored by dividing the sum total of item response values by the maximum possible score and transforming this value onto a scale of 0 to 100 (0 indicating “Best” and 100 “Worst” health status). The 19 domains of ePAQ and a summary of their constituent items are shown in Table 18.1.

ePAQ is interactive on a number of levels. The standard item format includes a question on how often a symptom occurs (symptom frequency) and a subquestion on how much of a problem this is (symptom impact). These subquestions are also hidden if subjects are asymptomatic (screen negative).



Electronic Pelvic Floor Symptoms Questionnaire

ePAQ

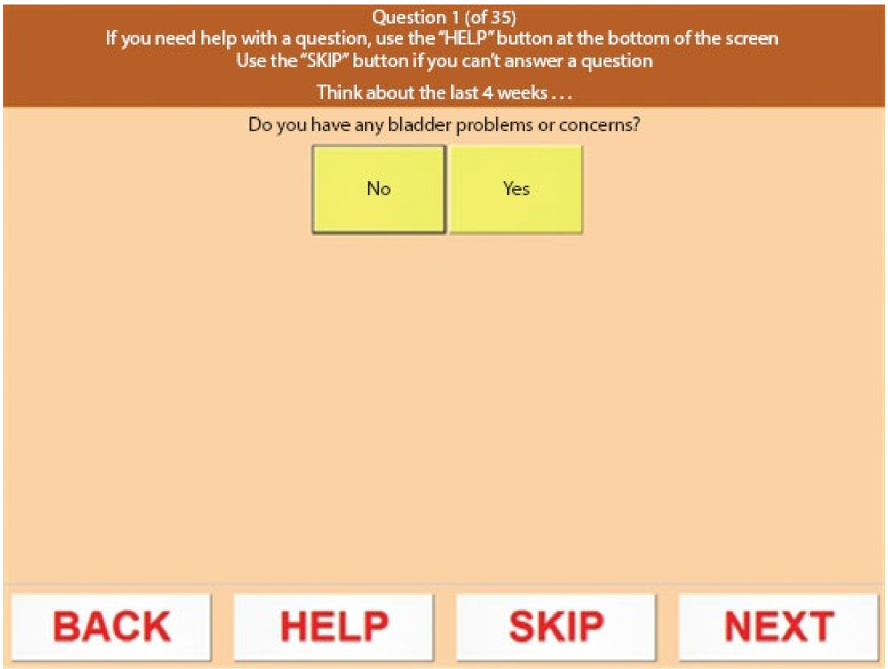
This questionnaire is designed to assess any problems you may have with your pelvic floor

There are 4 sections to this questionnaire

- Bladder & urinary symptoms
- Bowel symptoms
- Vaginal symptoms and prolapse
- Sex life

If you do not understand or want help with a question, press the button which looks like this:

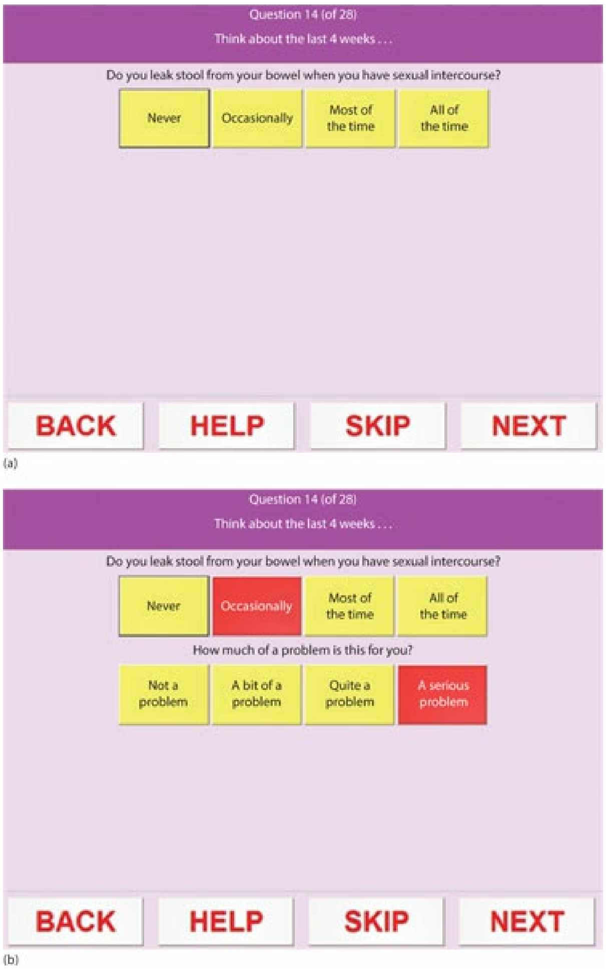
Figure 18.2 Introductory page of ePAQ introduces subjects to the questionnaire and the use of “Back,” “Next,” and “Help” buttons to navigate through the questionnaire.



Question 1 (of 35)
If you need help with a question, use the "HELP" button at the bottom of the screen
Use the "SKIP" button if you can't answer a question
Think about the last 4 weeks . . .

Do you have any bladder problems or concerns?

Figure 18.3 ePAQ screening item with navigation buttons "Back, Help, Skip, and Next." Screening items such as this contribute to inbuilt skipping rules, reducing respondent burden, while allowing the questionnaire to probe symptomatic areas or concerns.



Question 14 (of 28)
Think about the last 4 weeks . . .

Do you leak stool from your bowel when you have sexual intercourse?

Question 14 (of 28)
Think about the last 4 weeks . . .

Do you leak stool from your bowel when you have sexual intercourse?

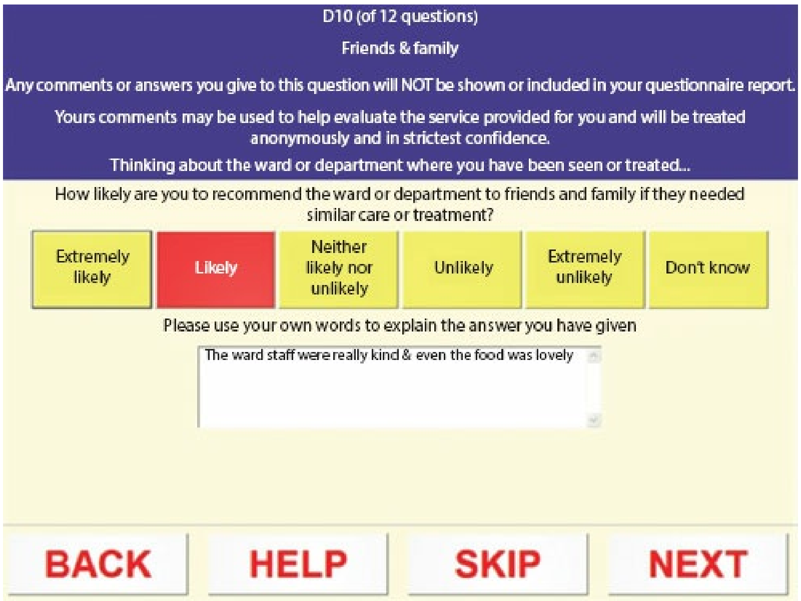
How much of a problem is this for you?

Figure 18.4 (a) Example of ePAQ item, illustrating its simple 4-point scale with standard question and response formats. (b) The questionnaire is interactive on a number of levels; when subjects report symptoms, a sub-question on impact “How much of a problem is this for you?” is shown.

The “friends and family test” has recently been incorporated, giving patients the opportunity to provide feedback on the care that they have received (Figure 18.5). The final item records patients’ willingness for their data to be used for nonclinical purposes, such as service evaluation and audit; 95% of patients agree to this (Figure 18.6).

REPORTS AND PROGRESS REPORTS

On completion, a summary ePAQ report is available, which can be viewed on screen or printed as a PDF. This presents summary data and 19 domain scores on one page, as well as a detailed report that includes responses to individual items, with a further page for each dimension. The clock face icons adjacent to the domain scores provide a visual measure of the *maximum* impact associated with any one of the constituent items of that domain: an empty circle; ○ = “Not a problem,” one-third of a full circle; ◔ = “A bit of a problem” two-thirds fill; ◕ = “Quite a problem” and a solid circle;●= “A serious problem” (Figure 18.7).



D10 (of 12 questions)

Friends & family

Any comments or answers you give to this question will NOT be shown or included in your questionnaire report.

Yours comments may be used to help evaluate the service provided for you and will be treated anonymously and in strictest confidence.

Thinking about the ward or department where you have been seen or treated...

How likely are you to recommend the ward or department to friends and family if they needed similar care or treatment?

Likely

Please use your own words to explain the answer you have given

The ward staff were really kind & even the food was lovely

Figure 18.5 NHS friends and family test. Data from this item are not shown in the ePAQ report but are stored on the database, thereby facilitating collection of information that may be of value in service evaluation, appraisal, and revalidation.

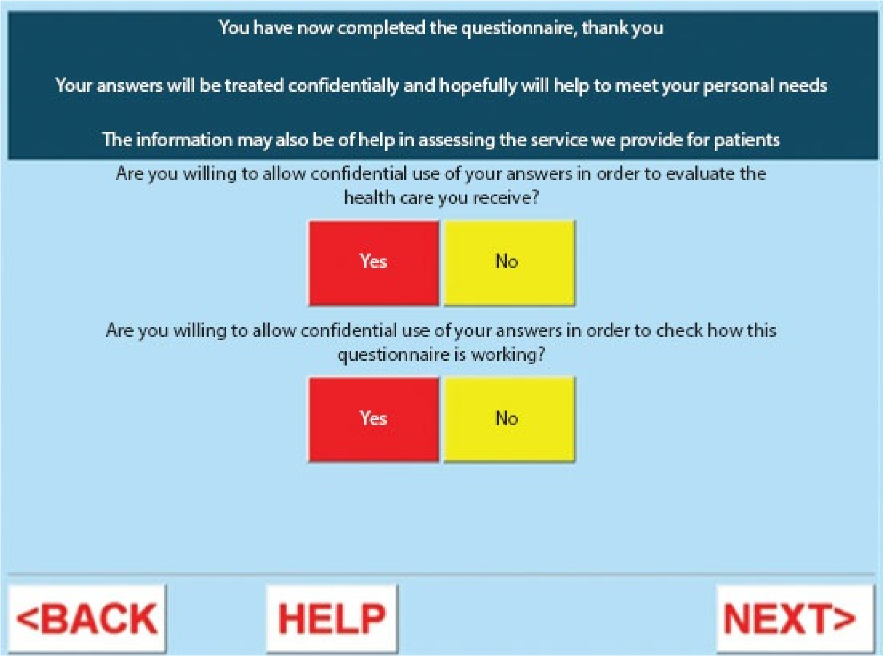
Domains	**Summary of Individual Items**
Urinary	
Pain	Bladder pain, burns with void, void relieves pain, reduced sensation
Voiding	Difficult voiding/void incomplete/strains to void/reduced stream/digitation to void
Overactive bladder	Urgency/urgency incontinence/hand wash incontinence/key in the door incontinence
Stress incontinence	Cough incontinence/sneeze/exercise/movement/walk
Quality of life	Impact on overall enjoyment of life/physical activities/social activities
Bowel	
IBS	Stool variability/regularity/pain pre-defecation/mucus or slime/bloating
Constipation	Stool hard/frequency/laxative use
Evacuation	Incomplete evacuation/straining/painful evacuation/duration of evacuation/perineal splinting/anal

	digitation/unable to evacuate
Continence	Incontinence liquid stool/flatus/solid stool/incontinence without warning/urgency/incontinence with urgency/ability to defer
Quality of life	Impact on overall enjoyment of life/physical activities/social activities
Vaginal	
Pain and sensation	Dryness, soreness/reduced sensation/dragging pain
Capacity	Tight entrance/tight inside/shortness
Prolapse	Something coming down/laxity/awareness of lump/complete prolapse
Quality of life	Impact on overall enjoyment of life/physical activities/social activities
Sexual	
Urinary	Incontinence during sex, avoids sex c/o bladder, partner avoids c/o bladder, bladder worries and sex, overall impact on sex
Bowel	Incontinence during sex, avoids sex c/o bowel, partner avoids c/o bowel, bowel worries and sex, overall impact on sex
Vaginal	Pain/discomfort and sex, avoids sex c/o vagina, partner avoids c/o vagina, vaginal worries and sex, overall impact on sex
Dyspareunia	Dryness/lack of sensation/discomfort and pain/tightness/obstruction
General sex life	Overall problems/loss of libido/satisfied overall/own health and sex/partner health and sex



You have now completed the questionnaire, thank you

Your answers will be treated confidentially and hopefully will help to meet your personal needs

The information may also be of help in assessing the service we provide for patients

Are you willing to allow confidential use of your answers in order to evaluate the health care you receive?

Yes No

Are you willing to allow confidential use of your answers in order to check how this questionnaire is working?

Yes No

Figure 18.6 Consent item—95% of patients agree to their data being used for nonclinical purposes, thereby enabling an ethical approach to activities such as audit and service evaluation.

When patients repeat ePAQ following intervention, consecutive questionnaires can be presented in a single *progress report*. The patient’s response to a *global rating of change* item is also highlighted at the top of this report. These data facilitate real-time outcomes monitoring for individual patients and are a key element in “Virtual Clinics” where ePAQ is combined with telephone consultation, for example, following incontinence or prolapse surgery or for women undergoing intravesical botulinum treatment for overactive bladder and again, if and when symptoms recur over time (Figure 18.8).

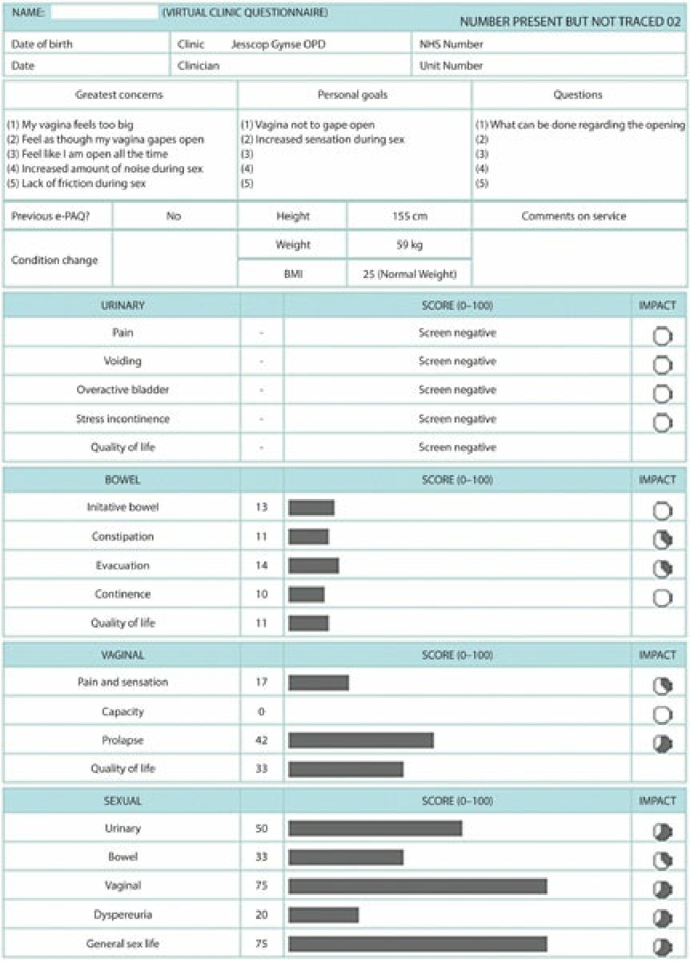
INTERNET COMPLETION

When originally introduced, ePAQ was exclusively used on touch-screen computer terminals used in clinics, substitute for keyboard and mouse. However, the majority of ePAQ users now complete the questionnaire via the Internet, linked to individual Trust-based installations on the NHS-N3 network.

All online data are collected anonymously and transferred to the NHS-N3 ePAQ database, where data are personalized and stored. Access to patient data is only possible for NHS registered users, each with their own username and password. Vouchers for online completion of ePAQ are issued by clerical, admin, or clinical staff, all of whom have personal logins. The system generates a unique voucher code for each patient, embedded in a preformatted letter, which can be printed, posted, or emailed. The voucher letter provides information about ePAQ and how to use it and can be modified to suit individual clinics or settings (Figure 18.9). Vouchers are issued to postoperative patients at the time of discharge from the ward, with instructions to complete the questionnaire via the Internet (http://www.epaq-voucher.co.uk) in advance of their next appointment. Most women, who have given the option of attending outpatients or the virtual clinic, choose the latter.

DEPLOYMENT

The feasibility of questionnaire use involves an understanding of the resources required to effectively deploy the instrument in a specific setting, achieving acceptable levels of compliance, value, and burden for patients and clinicians [17]. Ease of administration and interpretation is the key element in this, as well as overall cost, which should include societal and personal costs, and environmental issues such as travel. Generally though, Trusts are the most interested in institutional costs. With large-scale deployment, electronic questionnaires may offer economic advantages compared with facsimile and scanning scoring methods [4]. Costs include the supply and maintenance of hardware such as touch-screen terminals, labor costs, and software licensing and support. Current research is examining the health economic impact of ePAQ in different clinical settings, virtual clinics, and long-term follow-up of patients following surgery (Figure 18.10).



NAME: (VIRTUAL CLINIC QUESTIONNAIRE)

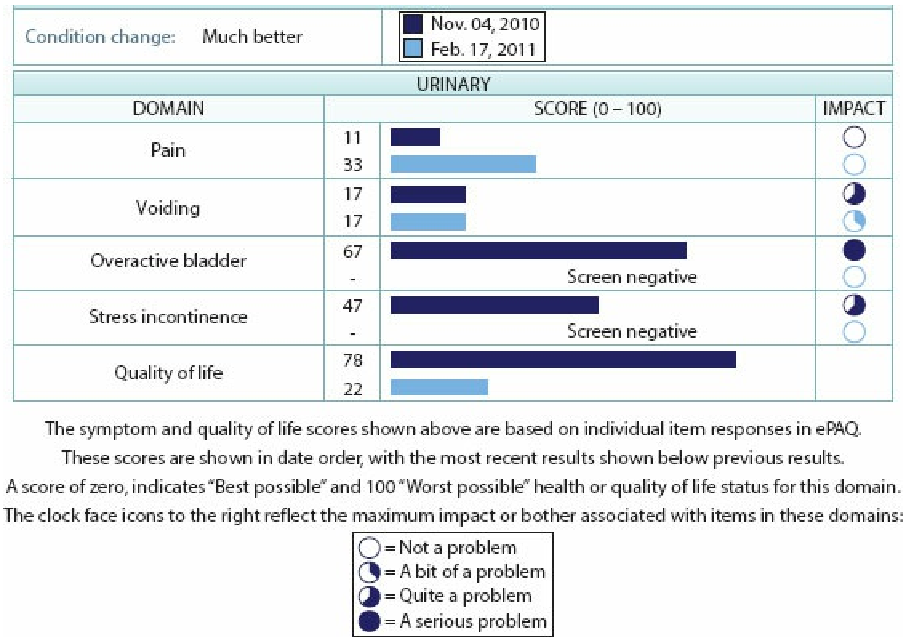
Figure 18.7 Summary report.

CLINICAL DECISION-MAKING

The ePAQ report serves as an adjunct to clinical evaluation—recording, processing, and relaying sensitive information relating to patients' own views of their condition. The consultation may be better informed, more efficient and effective as a result. Surveys of patients' views commonly find that patients find the questionnaire that allows them to focus on problems that concern them, often in areas that are difficult to discuss openly, such as fecal incontinence and sexual dysfunction. The inclusion of free text items relating to patients' personal goals enables the collection of qualitative data and a degree of self-expression beyond the scope of closed multiple choice questions. ePAQ reports are used alongside other information, such as frequency volume chart data, urodynamic findings, and clinical correspondence, to inform consultation, discussion, and decision-making (Figure 18.11).

The questionnaire helps to differentiate and measure related conditions such as constipation and obstructed defecation, dyspareunia and prolapse, and stress and urge incontinence. This has proved particularly valuable in deciding whether or not urodynamic investigation is required prior to incontinence surgery. An overview of global pelvic floor health helps in managing expectations in patients with multiple conditions, for example, informing discussion regarding outcomes for overactive bladder symptoms in women undergoing stress incontinence surgery.



Condition change: Much better

■ Feb. 17, 2011

URINARY

DOMAIN	SCORE (0 – 100)		IMPACT
Pain	11 33		○ ○
Voiding	17 17		◑ ◔
Overactive bladder	67 -	Screen negative	● ○
Stress incontinence	47 -	Screen negative	◑ ○
Quality of life	78 22		

The symptom and quality of life scores shown above are based on individual item responses in ePAQ.
These scores are shown in date order, with the most recent results shown below previous results.
A score of zero, indicates "Best possible" and 100 "Worst possible" health or quality of life status for this domain.
The clock face icons to the right reflect the maximum impact or bother associated with items in these domains:

○ = Not a problem
◔ = A bit of a problem
◑ = Quite a problem
● = A serious problem

Figure 18.8 Progress report used to assess following intravesical botox in overactive bladder.

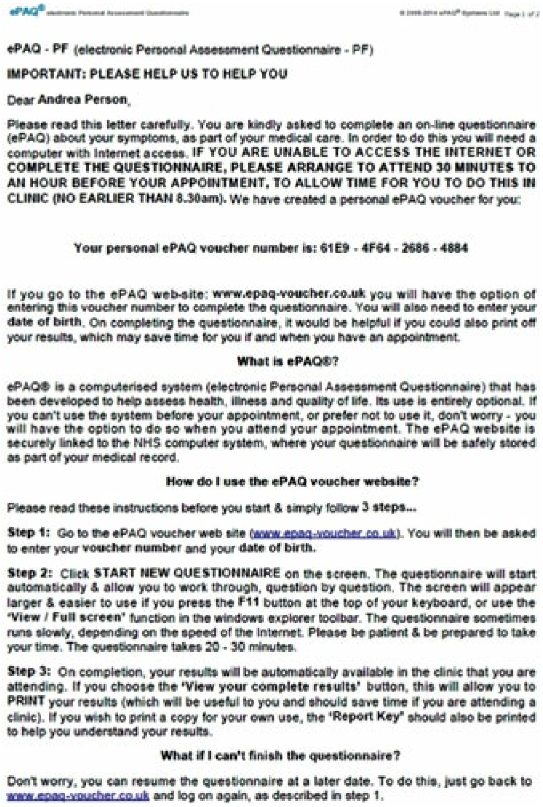
Pressures on clinical time can result in important issues such as fecal incontinence being overlooked in women with urinary incontinence, dyspareunia, and vaginal dryness not being considered in women with prolapse. The impact of symptoms shown alongside domain scores assists in prioritizing key areas from the patient's perspective; for example, some women with prolapse may be relatively asymptomatic or unbothered by prolapse-related symptoms and not requiring treatment. Women with dyspareunia and sexual dysfunction may be more appropriately prescribed Hormone Replacement Therapy than prolapse surgery. In relation to functional bowel problems, differentiating between obstructive defecation and constipation is important in women with rectocele. Measuring these parameters routinely, before and following intervention in larger cohorts of patients can provide greater insight into the impact that surgery for prolapse and incontinence has on wider aspects of pelvic floor function [16–19].

CLINICAL PATHWAYS

Ultimately, the use of this technology is likely to lead to increasing devolvement of patient care from secondary to primary care. Well-informed and targeted referrals for patients not responding to conservative measures enable the initiation of appropriate treatment via streamlined pathways. When used earlier in the care pathway, this may help with triage to appropriate services, for example, to physiotherapy for women with stress incontinence or to joint colorectal—urogynecology service for women with urinary and fecal incontinence. Greater use in primary care may support initial evidence-based management by GPs and other primary care clinicians, while facilitating and supporting integrated care with a single assessment tool throughout primary, secondary, and tertiary care, as well as across specialties such as urology, colorectal surgery, and urogynecology. When implementing new treatment modalities, such as percutaneous tibial nerve stimulation, having a PROM embedded in routine clinical care facilitates service evaluation in different areas using standard outcome measure [20]. Similarly, the routine collection of outcomes data is now mandatory for a number of urogynecological procedures and the British Society of Urogynaecology (BSUG) database now includes the option of entering ePAQ data in this context [21].

MULTIDISCIPLINARY TEAM WORKING

In women with recurrent or complex presentations (for example, coexistent urinary, colorectal, vaginal, and sexual problems), an objective and valid measure of all aspects of pelvic floor symptoms and their impact are extremely valuable. This may be particularly relevant in multidisciplinary case discussions, in related correspondence, and when coordinating and prioritizing a multidisciplinary approach. ePAQ enables a patient-focused approach to multidisciplinary team discussions, providing a comprehensive profile of symptoms and health-related quality of life for reference among other measures of health such as urodynamics, history, and physical findings.



ePAQ - PF (electronic Personal Assessment Questionnaire - PF)

IMPORTANT: PLEASE HELP US TO HELP YOU

Dear **Andrea Person**,

Please read this letter carefully. You are kindly asked to complete an on-line questionnaire (ePAQ) about your symptoms, as part of your medical care. In order to do this you will need a computer with Internet access. **IF YOU ARE UNABLE TO ACCESS THE INTERNET OR COMPLETE THE QUESTIONNAIRE, PLEASE ARRANGE TO ATTEND 30 MINUTES TO AN HOUR BEFORE YOUR APPOINTMENT, TO ALLOW TIME FOR YOU TO DO THIS IN CLINIC (NO EARLIER THAN 8.30am).** We have created a personal ePAQ voucher for you:

Your personal ePAQ voucher number is: 61E9 - 4F64 - 2686 - 4884

If you go to the ePAQ web-site: **www.epaq-voucher.co.uk** you will have the option of entering this voucher number to complete the questionnaire. You will also need to enter your **date of birth**. On completing the questionnaire, it would be helpful if you could also print off your results, which may save time for you if and when you have an appointment.

What is ePAQ®?

ePAQ® is a computerised system (electronic Personal Assessment Questionnaire) that has been developed to help assess health, illness and quality of life. Its use is entirely optional. If you can't use the system before your appointment, or prefer not to use it, don't worry - you will have the option to do so when you attend your appointment. The ePAQ website is securely linked to the NHS computer system, where your questionnaire will be safely stored as part of your medical record.

How do I use the ePAQ voucher website?

Please read these instructions before you start & simply follow **3 steps...**

Step 1: Go to the ePAQ voucher web site (www.epaq-voucher.co.uk). You will then be asked to enter your **voucher number** and your **date of birth.**

Step 2: Click **START NEW QUESTIONNAIRE** on the screen. The questionnaire will start automatically & allow you to work through, question by question. The screen will appear larger & easier to use if you press the **F11** button at the top of your keyboard, or use the **'View / Full screen'** function in the windows explorer toolbar. The questionnaire sometimes runs slowly, depending on the speed of the Internet. Please be patient & be prepared to take your time. The questionnaire takes 20 - 30 minutes.

Step 3: On completion, your results will be automatically available in the clinic that you are attending. If you choose the **'View your complete results'** button, this will allow you to **PRINT** your results (which will be useful to you and should save time if you are attending a clinic). If you wish to print a copy for your own use, the **'Report Key'** should also be printed to help you understand your results.

What if I can't finish the questionnaire?

Don't worry, you can resume the questionnaire at a later date. To do this, just go back to www.epaq-voucher.co.uk and log on again, as described in step 1.

Figure 18.9 ePAQ voucher, embedded in automatically generated letter, which can be edited to suit the specific requirements of the clinic. These voucher letters are issued by clerical staff and sent or given to patients along with their appointment details.

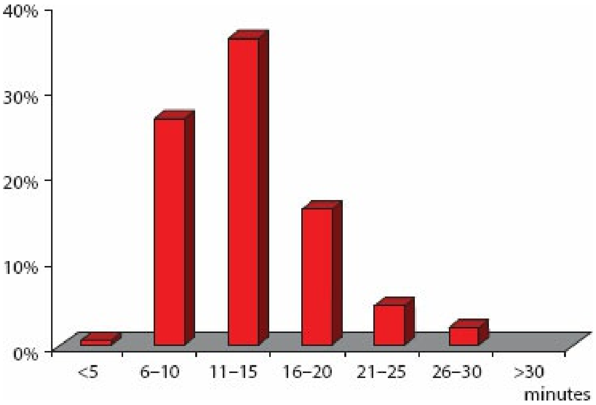


Figure 18.10 Completion times for ePAQ using touch-screen terminals in gynecology outpatients. Although the median completion time was 15 minutes, many patients take considerably longer than this and some require assistance from clinical staff or carers, which is recorded in the questionnaire.

VIRTUAL CLINICS

The Virtual Urogynaecology Clinic (VUC) combines electronic interviewing using ePAQ-PF with telephone consultation. Initial evaluation of VUC has shown high-patient satisfaction and acceptability, particularly in relation to communication and access. Early experience indicates the potential for improved efficiency as well as quality of care, particularly for follow-up patients. Patients generally find the system easy and rewarding to use. Women, given the option of attending the outpatient clinic or virtual clinic following prolapse surgery, most commonly choose the latter.

Surveys of ePAQ users in a number of units have identified the need to provide local administrative support, staff training justification of costs, and adequate patient completion time for those who are unable or unwilling to complete the questionnaire online. Informing patients of the value and importance of questionnaire completion, both before and following, was felt to be important, as was the need for adequate resources and staff education in achieving this. Qualitative evaluation of patient experience of ePAQ suggested that women felt that the questionnaire improved their understanding of their condition; improved communication with clinicians and preparedness for clinical consultation appeared to support improved focus and insight, which in turn contributed to the setting of realistic expectations [22].

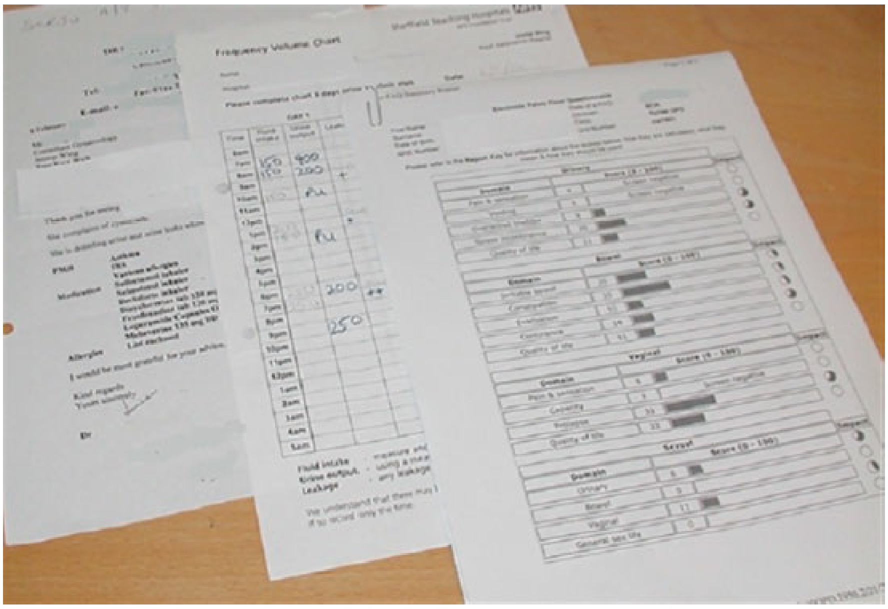

Figure 18.11 New patients in urogynecology usually precomplete ePAQ and frequency volume charts prior to consultations. When combined with referral letters, these elements provide significant insight into the

patient's condition, enabling a focussed and effective consultation.

Multisite survey data have shown that between 72% and 85% of women attending urogynecology clinics had internet access and 60%–80% of women will complete ePAQ online when posted a voucher letter accompanying their first clinic appointment. Attempts to improve response rates include the use of reminders and explanatory letters, using higher font size (12) and the use of colored, headed paper for correspondence. Emphasizing the value to patients themselves and encouraging active participation and engagement (rather than passive acceptance) in their own health and healthcare may have additional benefits, for both patients and providers. Although levels of connectivity and computer literacy have increased substantially in recent years, increasing age and low socioeconomic status remain important barriers, though being female is a consistent positive predictor of eHealth use [23]. Women may seek the help of family members or close friends, though this may impact on the accuracy of data provided.

OTHER INSTRUMENTS

ePAQ® is currently being used in 15 units in the United Kingdom. There is an interest in developing questionnaires for other clinical areas and conditions; a generic platform questionnaire builder now supports the development of instruments in a variety of fields. A number of additional prototype questionnaires such as preoperative assessment (ePAQ-PO), menstrual, pain, and hormonal (ePAQ-MPH), and ePAQ-Vulva have been created and are currently being evaluated to establish their clinical utility, validity, and reliability.

CONCLUSIONS

The primary goals of interventions for pelvic floor disorders are the relief of symptoms, restoration of function, and improvement in quality of life. A responsive patient-based measure of health as well as symptom severity and impact is a valuable addition in this context, providing initial assessment and patient-based measure of outcome, presented in a meaningful way. There is evidence that for sensitive issues, computer-assisted interviewing can enhance disclosure and openness. In recent years, IT literacy and access to and sophistication of electronic systems have advanced substantially, now making electronic interviewing in healthcare an increasingly realistic option, with a shift toward greater use of eHealth and online assessments. Long-term follow-up using this technology is currently being evaluated. Addressing issues of access and compliance, particularly for patients with low socioeconomic status and advancing age is an important challenge. The overall impact on provider costs, patient experience, the quality of healthcare provision, and subsequent outcomes is demanding of further research.

Questionnaires to Assess Pelvic Organ Prolapse

Alex Digesu

EPIDEMIOLOGY

Pelvic organ prolapse (POP) is a common finding especially in parous women who have delivered vaginally. It has been calculated that up to 50% of parous women have some degree of POP, but only 10%–20% seek help for their condition [1]. The prevalence of POP is not well known as the data reported vary significantly according to the criteria utilized in various studies, ranging from 3% to 50%. In fact, POP when defined by symptoms has a prevalence of 3%–6%, and it rises up to 50% when based upon vaginal examination [2].

The risk of developing POP increases significantly with age and parity [3,4]. It has been estimated that up to 40% of women more than 50 years of age are affected by POP [5]. Considering that the women life expectancy is increasing, the prevalence of POP will increase significantly in the future years. By 2050, the number of women suffering from symptomatic POP in the United States is expected to increase by a minimum of 46% [6].

It has been calculated that surgery for POP is performed twice as commonly as continence surgery with a lifetime risk of undergoing prolapse repair of about 11% [7]. The prevalence of POP surgery varies from 6% to 18%, and the incidence ranges from 1.5 to 1.8 per 1000 women [1].

Bladder, bowel, and sexual symptoms are often associated with POP. Ellerkmann et al. found that in 237 women with POP, 73% had urinary incontinence (UI), 86% urgency and/or frequency, 34%–62% voiding difficulties, and 31% fecal incontinence. In view of the high prevalence of these associated symptoms, it is essential to fully evaluate the bladder, bowel, and sexual function while assessing women with POP [8].

Although POP and its associated symptoms are not life threatening, they may have a significant impact on quality of life (QoL) causing physical, social, psychological, role, domestic, personal, and/or sexual limitations [9,10].

Therefore, in recent years more attention has been paid to the complex relationships between POP and its often coexisting symptoms as well as on the impact of POP on women's QoL. It has been reported that there is a significantly weak to moderate correlation between the degree of POP, poor QoL, and severity of bladder, bowel, and sexual symptoms. However, the data reported in the literature are still controversial [2,8,11–15]. Finally, the postoperative QoL and patient's satisfaction with prolapse surgery are not correlated with a postoperative anatomical success alone but improve significantly only if the symptoms disappear and/or improve [16].

QUESTIONNAIRES

The evaluation of women with POP entails a complete assessment of all pelvic floor dysfunctions. The only valid way of measuring the severity of symptoms and their impact on QoL is through the use of psychometrically robust self-completed questionnaires [10,17–21].

Therefore, in the last decade, the evaluation of QoL in women with POP using validated self-completed questionnaires has become more popular in both clinical and research settings as the most important treatment goal for women has been shown to be the relief of symptoms and the improvement of their QoL [2,16]. It has also been suggested that QoL should be considered as an end point in all clinical trials [22].

Several validated and reliable generic as well as condition-specific health-related QoL (HRQoL) questionnaires have been described to assess POP to date [10,17–24]. Their use in clinical practice has also been recommended in the recent joint report of the International Continence Society (ICS) and International Urogynecological Association (IUGA) (grade C) [23,24].

In 2005, the Symptom and Quality of Life Committee of the International Consultation on

Incontinence (ICI) performed a systematic review of questionnaires related to urinary/anal incontinence, vaginal, and pelvic floor problems and concluded that "although considerable advances have been made in the assessment of urinary incontinence with 18 questionnaires now achieving the highest level (grade A) of scientific rigor, the development of questionnaires in the area of anal incontinence, vaginal and pelvic floor problems was at a much earlier stage." None of those could be considered as highly recommended (grade A); only two questionnaires were considered of established validity and reliability and consequently included in the grade B area; five of them were considered in the early stages of development and considered as grade C [25]. A summary of the questionnaires used to assess women with POP is shown in Table 19.1.

Pelvic Floor Distress Inventory and Pelvic Floor Impact Questionnaire

The *Pelvic Floor Distress Inventory* (PFDI) and *Pelvic Floor Impact Questionnaire* (PFIQ) were developed in 2001 by Barber et al. [17,18]. These questionnaires evolved from two questionnaires designed to evaluate the impact of UI on QoL: the *Urogenital Distress Inventory* (UDI) and the *Incontinence Impact Questionnaire* (IIQ) [26,27].

The PFDI was designed to evaluate the symptom distress or bother in women with pelvic floor dysfunction. It includes all of the items of the original UDI questionnaire and has additional questions related to POP and colorectal dysfunction. The PFDI contains 46 items divided into three domains: (1) UDI (28 items), (2) Colorectal–Anal Distress Inventory (CRADI) (17 items), and (3) POP Distress Inventory (POPDI) (16 items).

Table 19.1 Summary of the Questionnaires used to Assess Women with POP

Questionnaire	Purpose	No. of items	Domains	Scoring system
PFDI	To measure degree of bother and distress caused by pelvic floor dysfunction	46	3 scales Urogenital Distress Inventory Colorectal–Anal Distress Inventory	Each scale: 0 (least distress) to 100 (greatest distress)
PFDI-20 (short form)		20	POP Distress Inventory	
PFIQ	To assess the impact of the pelvic floor disorders on women's life	93	3 scales Urinary Impact Questionnaire POP Impact Questionnaire	Each scale: 0 (least impact) to 100 (greatest impact)
PFIQ-7 (short form)		7	Colorectal–Anal Impact Questionnaire	
P-QoL	1. To assess POP symptoms severity 2. To evaluate QoL of women with POP 3. To better identify those women needing treatment 4. To assess the treatment outcome of women with POP	20	General health perceptions Prolapse impact Role limitations Physical limitations Social limitations Personal relationships Emotions Sleep/energy Severity measures	Each item: four-point Likert Scale—"none/not at all," "slightly/a little," "moderately," and "a lot" Scoring system each domain score: 0–100 Higher scores: poor QoL

ICIQ-VS	ICI module to assess the severity of POP symptoms (vaginal and sexual), to measure their impact on QoL, and to evaluate the treatment outcome	27	Vaginal symptoms	0–53 vaginal symptoms subscale
Sexual matters	0–58 sexual matters subscale			
Final version		14	Impact of vaginal symptoms on QoL 2 additional introductive filter questions	0–10 overall impact on quality of life subscale Higher scores: poor QoL
POP-SS	To measure primary outcome of POP treatments	7	Feeling of something coming down from the vagina? Vaginal pain worse when standing? Heaviness in lower abdomen? Heaviness in lower back? Need to strain to empty your bladder? Bladder voiding incomplete? Bowel voiding incomplete?	Five-point Likert scale Total score (range 0–28) calculated by summing the seven individual scores
PFDQ	To compare symptoms related to pelvic floor dysfunctions with the location and severity of the coexisting POP	65	8 domains UI Irritative urinary symptoms Voiding dysfunction POP Fecal incontinence Defecatory dysfunction Pelvic pain Sexual dysfunction	Likert scale to quantify the severity (none, 0; minimally, 1; moderately, 2; severely, 3), the duration of symptoms (never, 0; <25% of time, 1; <50% of time, 2; <75% of time, 3; 100% of time, 4), and the impact on QoL

Abbreviations:PFDI, Pelvic Floor Distress Inventory; PFIQ, Pelvic Floor Impact Questionnaire; P-QoL, Prolapse Quality of Life; ICIQ-VS, International Consultation on Incontinence—Vaginal Symptoms; POP-SS, Pelvic Organ

Prolapse–Symptom Score; PFDQ, Pelvic Floor Dysfunction Questionnaire; DPQ, Danish Prolapse Questionnaire; PISQ, Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire; ePAQ-PF, electronic Personal Assessment—Pelvic Floor; APFQ, Australian Pelvic Floor Questionnaire; VAS, visual analog scale; PGI-I, Patient Global Impression of Improvement.

The PFIQ was designed to assess the impact of the pelvic floor disorders on women's life. Similar to PFDI, it contains all the items included in the original IIQ and has additional items related to other pelvic floor dysfunction. In all, the PFIQ has 93 items divided into three domains: (1) Urinary Impact Questionnaire, (2) POP Impact Questionnaire, and (3) Colorectal–Anal Impact Questionnaire.

PFDI and PFIQ have shown good validity and reliability (both content and construct). Despite the strengths of these two complementary questionnaires, their comprehensive nature and relative length (23 minutes to be completed) may be inefficient and impractical in the clinical practice. Therefore, the same authors developed and validated the shorter versions 4 years later [7]. The PFDI-20, which contained 20 items instead of 46, and the PFIQ-7, which included 7 items instead of 93, are short forms that maintained their excellent correlation with the PFDI and PFIQ long forms and have proved to be reliable and responsive to change. They have a 3-month recall period of symptom, thus being helpful instruments to use particularly when evaluating the outcomes of conservative therapy that may require some time to show any clinical benefit [17,18].

These instruments have been considered of great help in the evaluation of the largest spectrum of pelvic floor dysfunctions, ranging from POP to bladder and bowel disorders, which usually coexist. To date, these questionnaires have been translated into Korean, Spanish, Greek, Danish, Turkish, Swedish, and French [28–36].

Prolapse Quality of Life

The prolapse QoL (P-QoL) questionnaire was developed in 2004 by Digesu et al. in response to the necessity for a shorter and easier questionnaire able to investigate the severity of POP symptoms and their impact on women's QoL, which was missing in the PFDI and PFIQ [10].

P-QoL contains 20 questions divided into nine domains: general health (1 item), prolapse impact (1 item), role limitations (2 items), physical limitations (2 items), social limitations (3 items), personal relationships (2 items), emotional limitations (3 items), sleep/energy disturbance (2 items), and severity measurement (4 items). The structure is similar to the King's Health Questionnaire. The answers are categorized using a four-point Likert scale: "none/not at all," "slightly/a little," "moderately," and "a lot." A score is calculated for each domain ranging from 0 to 100. A higher score indicates a greater impairment of QoL or poor QoL.

In addition to the QoL items, the P-QoL also includes 18 symptom questions: 11 urogenital (bladder, sexual) and 7 bowel. The responses for those 18 questions are categorized using a five-point Likert scale: the same four options used for QoL items plus a "not applicable" option if the women do not have the symptom. These symptom questions do not compose any dimension or a score.

The P-QoL has been shown to be a valid, reliable self-completed questionnaire that is easy to understand and to complete. P-QoL domain scores have also been demonstrated to be significantly different between symptomatic and asymptomatic women, thus showing a good content reliability as well as being significantly higher (poor QoL) in women with more advanced/severe POP stages thus demonstrating a good construct reliability.

To date, the P-QoL has been cross-culturally translated and validated into several languages including English, Italian, Dutch, Thai, Slovakian, Portuguese, German, Turkish, Persian, Japanese, Spanish, and French and used in clinical as well as research practice. It is a useful tool: (1) to assess POP symptoms severity, (2) to evaluate QoL of women with POP, (3) to better identify those women needing treatment, and (4) to assess the treatment outcome of women with POP [10,37–45].

Pelvic Floor Dysfunction Questionnaire

The Pelvic Floor Dysfunction Questionnaire (PFDQ) was designed by Ellerkmann et al. [8] in 2001 to compare symptoms related to pelvic floor dysfunctions with the location and severity of the coexisting POP. This is a symptom-specific Likert scale questionnaire that included 65 questions that were assembled from commonly used validated instruments. The PFDQ is divided into eight domains, each related to a specific dysfunction. These domains include UI, irritative urinary symptoms, voiding dysfunction, POP symptoms, fecal incontinence, defecatory dysfunction, pelvic pain, and sexual dysfunction. A Likert scale is used both to quantify the severity (none, 0; minimally, 1; moderately, 2; severely, 3), the duration of symptoms (never, 0; <25% of time, 1; <50% of time, 2; <75% of time, 3; 100% of time, 4), and the impact on QoL. The authors tested this questionnaire on 237 women and concluded that (1) POP symptoms do not necessarily correlate with compartment-specific defects and (2) increasing severity of POP is weakly to moderately associated with urinary, defecatory, and sexual dysfunction [8]. The psychometric properties (validity and reliability) of this questionnaire have never been tested.

Danish Prolapse Questionnaire

The Danish Prolapse Questionnaire was developed and validated by Mouritsen and Larsen in 2003 to evaluate the symptom distress in women with POP [46].

It is a symptom-bother questionnaire that contains 34 questions divided into four domains: (1) mechanical symptoms, (2) lower urinary tract symptoms, (3) bowel symptoms, and (4) sexual symptoms. The severity of each symptom is graded according to frequency (1, never or less than once/month; 2, less than once/week; 3, once or more/week; 4. daily).

An additional four-point bother score was included to assess how each symptom affected QoL. The questionnaire was tested on 110 women with POP and symptom’s severity was compared to the POP stage.

Despite the frequency of bladder bowel and sexual dysfunctions in patients with POP and the related QoL impairment, this study failed to show any specific correlation between coexisting symptoms and POP location and severity.

The psychometric properties (validity and reliability) of this questionnaire have never been tested.

International Consultation on Incontinence Questionnaire: Vaginal Symptoms Questionnaire

The International Consultation on Incontinence Questionnaire–Vaginal Symptoms (ICIQ-VS) questionnaire was developed and validated by Price et al. [20] in 2006. It is a self-completed questionnaire designed as an ICI module to assess the severity of POP symptoms (vaginal and sexual), to measure their impact on QoL, and to evaluate the treatment outcome.

The ICIQ-VS questionnaire was originally structured into three domains including 14 items related to vaginal symptoms, 10 items related to sexual matters, a single question to evaluate the impact of vaginal symptoms on QoL, and 2 introductive filter questions. The scores range from 0 to 53 (vaginal symptom score), 0 to 58 (sexual matter score), and 0 to 10 (QoL score). A high score indicates greater impairment/poor QoL, while a low score indicates a good QoL. In view of the redundancy and overlapping of some items, the final version of the ICIQ-VS questionnaire was restricted to 14 items. It has been demonstrated to be a simple, reliable, valid, and widely applicable self-completed questionnaire able to measure the severity of vaginal and sexual symptoms in women with POP and to evaluate their impact on QoL. It has shown a high internal consistency (Cronbach’s alpha 0.70 and 0.84 for vaginal and sexual symptoms, respectively) and a good sensitivity to change.

Australian Pelvic Floor Questionnaire

The Australian Pelvic Floor Questionnaire can be used as a self- and/or interviewer-completed questionnaire. Both versions have been proved to be simple, easy to complete, valid, reliable, and sensitive to change [21,47]. They can be used in both clinical and research practice to evaluate all pelvic floor symptoms such as bladder, bowel, and sexual function, prolapse symptoms, symptom severity, impact on QoL, and symptoms bother. The self-completed version is preferred when evaluating the treatment outcome independently of health-care providers. The questions are grouped in four domains: bladder function (15 items), bowel function (12 items), prolapse symptoms (5 items), and sexual function (10 items). A four-point scoring system is used to assess the frequency, severity, and bothersomeness of pelvic floor symptoms for the majority of the items. Frequency of defecation, bowel consistency, lubrication, and sexual abstinence are excluded from the score.

The score for each of the four domains ranges between 0 and 10. The maximum total pelvic floor dysfunction score is 40 or 30 if a woman is not sexually active.

POP/UI Sexual Questionnaire

The POP/UI Sexual Questionnaire (PISQ) is a condition-specific, reliable, valid, and self-completed questionnaire designed and developed by Rogers et al. [48] in 2001 to assess sexual function in women with POP and/or UI. The PISQ contains 31 items categorized in three domains (subscales): (1) behavioral/emotive (15 items), (2) physical (10 items), (3) partner related (6 items). Responses are graded on a five-point Likert scale from “never” to “always.” The validation of the PISQ was a two-phase process including 83 and 99 women respectively. In phase 1, the PISQ scores were correlated with the IIQ-7 scores. In phase 2, the PISQ was compared with the Sexual History Form-12 (SHF-12). In view of the high correlation between domain scores of PISQ and IIQ-7 and SHF-12 scores, the authors concluded that PISQ is a valid, reliable, and useful instrument for the assessment of women with POP.

Two years later, Rogers et al. developed and validated the short form of the PISQ. The PISQ-12, which includes 12 items, revealed good to excellent correlation with PISQ-31 scores, good reliability, and reproducibility [49].

Electronic Personal Assessment Questionnaire: Pelvic Floor

The idea of an electronic Personal Assessment Questionnaire (ePAQ) by using a computer interview process started in 2008. The ePAQ–pelvic floor (ePAQ-PF) questionnaire was developed from the Birmingham Bowel and Urinary Symptoms Questionnaire (BBUSQ-22) [50], the Sheffield Prolapse Symptoms Questionnaire (SPSQ) [51], and the Female Sexual Function Index (FSFI) questionnaire [52].

The BBUSQ-22 is a 22-item questionnaire developed to assess patients with functional bowel and urinary symptoms.

The SPSQ specifically assesses symptom severity in women with anatomical and functional pelvic floor disorders. It is divided into four domains: (1) lump and pain, (2) bladder function, (3) bowel function, and (4) sexual function. It also includes a final evaluation of the impact of POP symptoms on women’s QoL.

The FSFI, a validated 19-item questionnaire, is developed as a multidimensional tool to evaluate female sexual function. It provides scores on six domains of sexual function (desire, arousal, lubrication, orgasm, satisfaction, and pain) as well as a total score.

The ePAQ-PF questionnaire was developed as a valid instrument to evaluate the impact of urinary, bowel, vaginal, and sexual symptoms on QoL. It also includes additional domains on dyspareunia and general sex life. ePAQ-PF includes four dimensions (urinary, bowel, vaginal, and sexual [each consisting of 35, 33, 22, and 28 items, respectively]) and 19 scored domains. All items score between 0 and 3 (0 indicating best and 3 indicating worst health status). These domain scores are calculated, by dividing the sum of all items in the domain by the total possible item score and multiplying this by 100, to produce a scale 0–100. A higher score indicates the worst possible health status. The “bothersomeness” of a symptom is scored using a four-point scale (0, not a problem; 1, a bit of a problem; 2, quite a problem; and 3, a serious problem).

A cross-sectional study was performed to assess the validity and reliability of the ePAQ-PF. A total of 599 women with pelvic floor disorders were studied. Internal reliability, levels of missing data, secondary factor analysis, floor and ceiling effects, descriptive statistics, item-to-total correlation scores, item discriminant, and convergent validity were measured. All 19 domains were internally reliable with Cronbach’s alpha scores ranging from 0.71 to 0.93. Missing response rates ranged from 0.2% to 1.3%. All items were found to be most highly correlated with their own corrected scale. Therefore, the authors concluded that the ePAQ-PF is a valid and reliable instrument to assess (1) the severity and bother of pelvic floor disorders, (2) the impact of pelvic floor disorders on women’s QoL, and (3) the treatment outcome [53,54].

The advantages of this computerized instrument are the reduction of missing data and the high satisfaction ratings, probably due to the greater privacy setting. Furthermore, ePAQ allows direct input of the data collected into a database, while paper-based questionnaires need to be entered manually onto the computer database.

Nevertheless, the cost of technology and the necessity of patient technological skills might be a limitation for the wide spread of the ePAQ-PF, especially considering that the majority of women with POP are elderly.

OTHER INSTRUMENTS TO ASSESS POP

Visual Analog Scale

A visual analog scale (VAS) is a highly repeatable method that was originally developed for the evaluation of pain. It has been recently adapted by urogynecologists as an easy method to use in the routine clinical practice to assess the severity of pelvic floor disorders, degree of bother, and the treatment outcome and satisfaction. Responders are asked to indicate the severity of their disease on a 10 cm VAS; 0 indicates no complaints, whereas 10 indicates unbearable symptoms. Although it cannot be compared to more complex validated questionnaires that investigate a wide range of symptoms, VAS score has shown to be a reliable tool to assess subjective impact of POP symptoms on QoL. In a recent study, Ulrich et al. [55] used a VAS to assess the degree of bother of POP. The authors studied 636 women with POP. VAS bother scores for POP symptoms were significantly associated with both clinical and ultrasound measures of pelvic organ descent. Therefore, the authors concluded that VAS is a valid, repeatable, and a simple tool to measure the POP bother in the clinical practice [55].

POP Symptom Score

The POP–Symptom Score (POP-SS) was designed and validated in 2008 by Hagen et al. to assess POP symptoms before and after treatment. It includes a set of key questions covering the symptoms caused or worsened by POP that could be used as outcome measures for randomized trials to compare different treatments of POP [56].

The POP-SS consists of seven items, each with a five-point Likert response set (0, never; 1, occasionally; 2, sometimes; 3, most of the time; and 4, all of the time). A total score (range 0–28) is calculated by summing the seven responses. An additional question to identify the symptoms that cause most bother is also included. The POP-SS has showed a good internal consistency (Cronbach's alpha 0.723–0.823), has showed good construct reliability, and is sensitive to change. To test its validity, the POP-SS was evaluated in three studies based on three different patient clusters: postpartum women, patients treated with pelvic floor muscle training (PFMT), and patients undergoing surgical repair of POP. Those studies demonstrated that POP-SS is a very useful instrument to measure treatment effectiveness [57].

Patient Global Impression of Improvement

The Patient Global Impression of Improvement (PGI-I) [58], originally described in 1976 (Clinical Global Impression), is a seven-point scale that may be used to rate the response of a condition to a therapy. PGI-I is a simple, direct, easy-to-use scale. It is a single-question, self-completed questionnaire that can be used in both clinical and research practice. The PGI-I measures the patient impression of improvement after treatment. It is rated as (1) very much improved, (2) much improved, (3) minimally improved, (4) no change, (5) minimally worse, (6) much worse, or (7) very much worse.

The PGI-I have been widely used in psychiatry and several other fields in medicine. Its validity and reliability has also been tested on women with stress UI. In 2009, Srikrishna et al. validated the PGI-I in women with POP and showed that it is a valid, reliable, and sensitive to change tool to assess in a simple manner the outcome of POP surgery [59].

POP Questionnaires in Clinical and Research Practice

QoL questionnaires have provided important insights for a better understanding of (1) impact of POP on daily life, (2) relationship between anatomical defects and coexisting symptoms, and (3) outcomes of various therapeutic modalities available to women with POP. A summary of the data reported in the literature is described in the following text.

POP Questionnaires and Pessary Usage

It has been demonstrated that the stage of POP does not determine the success of pessaries and therefore should not influence the clinical decision when choosing candidates for pessary use [60]. QoL questionnaires have been used in the past to evaluate the short- and long-term outcomes in women with POP managed with pessaries. Those studies have shown the following: 1. high treatment satisfaction (70%–92%) [61,62], 2. improvement of sexual function (both frequency and satisfaction) demonstrating that sexual activity should not be considered a contraindication to pessary use [63,64], and 3. improvement in bladder and prolapse symptoms [62,65–68].

Few studies have compared QoL outcomes between surgery and pessary use in women with POP, and the data are controversial. Abdool et al. [63] reported similar improvements in both groups while Barber et al. [69] found that surgery is associated with greater QoL improvements when compared to pessary use.

POP Questionnaires and Physiotherapy

POP questionnaires have also been used to evaluate the outcomes of physiotherapy, showing a significant improvement of POP symptoms and QoL in women with POP [70,71].

Brækken et al. [72] studied women with POP quantification (POP-Q) < IV stage, with no previous surgery, and who were able to contract pelvic floor muscles. This was a randomized controlled trial using a four-point scale questionnaire to assess the frequency and bother of POP symptoms before and after PFMT. Those women were randomized to an intervention group (weekly physiotherapy visits for 3 months followed by fortnightly visits for 3 months) or to a control group with no intervention. The authors reported a significant greater improvement of POP-Q stages as well as severity and bother of POP symptoms in the PFMT group compared to the control group.

In another interesting randomized controlled trial, Barber et al. used PISQ-12 and incontinence QoL (I-QoL) before and after PFMT in women with POP undergoing surgery. The authors concluded that in women who had preoperative PFMT sexual function, vaginal examination findings, and QoL improved significantly compared to those who had surgery alone [73].

POP Questionnaires and Surgery

Several studies looked at the effect of POP surgery on women's QoL. Although sometimes data reported have been controversial, overall the majority of the studies confirmed that POP symptoms (bladder, bowel, vaginal), sexual function, and QoL improve significantly after POP surgery (i.e., vaginal hysterectomy, pelvic floor repair, sacrocolpopexy [abdominal, laparoscopic, and robotic], sacrospinous ligament fixation (SSLF), mesh repair, and colpocleisis) [74–83].

These data have also been confirmed by a recent meta-analysis that demonstrated that POP surgery improves women's QoL [84].

An interesting study from Fayyad et al. showed that POP surgery improved also POP symptoms. Increased urinary frequency, urgency, poor urinary stream, and incomplete bladder emptying improved significantly after anterior and posterior repair. Urge incontinence improved with anterior repair but did not improve with posterior repair. Stress UI did not improve after anterior or posterior repair. Bowel symptoms improved after posterior repair, and vaginal symptoms improved with any type of correction [85].

Few studies have reported a new onset of dyspareunia and worsening sexual function scores following SSLF and mesh repair [86,87].

Therefore, additional longitudinal larger studies are needed to further evaluate the outcomes of these procedures.

Colpocleisis is known as an obliterative procedure that may affect the sexual life and woman's QoL. Surprisingly, Fitzgerald et al. [88] studied 152 women before and after colpocleisis using PFDI and PFIQ and reported that 95% of those were either "very satisfied" or "satisfied" with the surgical outcome at 1-year follow up. Interestingly, 87% reported no change and 10% an improvement in sexual function. Similar results were confirmed by Barber et al. [89] who looked at QoL before and after colpocleisis and reported that such obliterative surgery has similar improvements in QoL with no increase in depressive symptoms compared to other pelvic reconstructive surgery.

CONCLUSIONS

POP is a common condition affecting women's QoL. Vaginal, urinary, bowel, and sexual dysfunctions are coexisting symptoms that may or may not be related to the descending pelvic organs but do affect the patient's daily life causing physical limitations, social limitations, personal limitations, depression, and low self-esteem.

Defining the "success" of POP treatment is not as simple as it seems. Historically, the majority of authors focused exclusively on anatomical success ignoring other important areas such as presence, absence, and severity of associated symptoms, sexual function, QoL, and patient's satisfaction. Considering that for a patient the most important outcome is the relief of her symptoms and improvement of her QoL [16], all the earlier findings should not be discounted. Therefore, the assessment and management of women with POP should not merely be determined by vaginal examination findings (defined as *clinician-reported outcomes* [CRO]) but more importantly be focused on the evaluation of the coexisting symptoms (defined as *patient-reported outcomes* [PRO]) using valid and reliable instruments able to measure their severity and burden as recommended by the Food and Drug Administration [90].

The use of questionnaires to assess subjective (PRO) and objective (CRO) outcomes by measuring the severity of associated symptoms (presence, burden, and severity), QoL, and treatment satisfaction in women with POP has been recently advocated in a joint report from the ICS and IUGA [24]. Their use in both clinical and research practice has been also recommended and encouraged by other organizations such as the National Institutes of Health (NIH) and World Health Organization's ICI [91].

Those questionnaires can be divided into four categories: (1) symptom-specific questionnaires (i.e., VAS), (2) HRQoL questionnaires, (3) sexual function questionnaires, and (4) Global Impression of Improvement.

HRQoL questionnaires are instruments able to assess the physical, emotional, social, sexual, and occupational limitation on a patient's QoL.

They can be classified into two types: generic and condition-specific questionnaires. Generic instruments can be used for different conditions but may lack sensitivity [18]. The two generic HRQoL instruments that have been used most frequently in women with POP are the SF-36 and the European QoL.

The condition-specific HRQoL questionnaires are designed to measure the impact on QoL of a specific health condition, providing a deeper assessment of the targeted disease, hence being more responsive to change than generic questionnaires. The use of ePAQ has been advocated and has several advantages compared to the paper-based questionnaires. However, the cost of technology and patient technological know-how should also be taken into account.

Long forms questionnaires may be desirable for research studies where detail is needed while short forms may have wider applicability in clinical practice, which is important to minimize respondent burden and cost. It is generally desirable to use a validated, simple, self-completed, psychometrically robust, easy-to-understand, and complete questionnaire that is widely accepted and has been used in the targeted population [91].

Only a few questionnaires are available for POP compared to UI. The majority of those have been assessed for validity and reliability, are fairly lengthy, cover a range of symptoms, and include a number of subscales related to urinary and bowel disorders. However, their ability to detect changes can vary [91].

Several studies have demonstrated that POP questionnaires are useful tools in clinical as well as research practice: (1) to evaluate the severity of symptoms, (2) to assess the symptoms' impact on QoL, (3) to screen and to identify those women who would benefit from treatment, and (4) to detect posttreatment changes.

Due to the amount of validated POP questionnaires developed in recent years, the clinician's choice should be guided by the desired outcome they would like to measure as well as based on the instrument they are more familiar with.

It is important to remember that administering too many questionnaires to a patient may be unhelpful since they can lead to patient's fatigue and possibly erroneous answers.

20 Economic Aspects of Urinary Incontinence

Kate H. Moore

INTRODUCTION

Since the publication of this chapter, concerning the economics of incontinence, in the previous edition of this book, the global financial crisis of 2008 has impacted upon health-care budgets in many countries. Now, more than ever, patients and health-care providers are seeking "value for money." In the current economic climate, we all need to be aware of the costs of the treatments that we recommend and be able to judge whether a new treatment is truly cost-effective.

Although health economics is sometimes considered a rather "dry" subject, this chapter is written from the clinician's perspective in an attempt to make the concept "come alive" for those working "at the coalface." We are all struggling to fight for enough money to care for our patients properly. As the population becomes more aged, the prevalence of urinary incontinence (UI) will rise, but our health-care budget will probably not keep pace with the demand for continence services. Most countries in the developed world have "controlled" budgets for health. As we all know, the prevalence of lethal conditions such as cardiovascular disease and stroke is also rising with the aging population. Because incontinence is not generally lethal, we must be able to compete with clinicians in other fields of medicine for increasingly precious health-care resources.

The recent controversy surrounding the use of medicated stents for coronary artery disease is a good example. A decade ago, the evidence appeared to show that inserting a medicated stent was a good way to avoid coronary artery bypass graft (CABG) surgery, resulting in large savings to the health economy. The need for long-term clopidogrel therapy, with its associated hemorrhagic risks if the patients needed urgent surgery for another condition, was considered a "necessary evil" to allow this cost saving. However, in the last few years, it was found that, in the long term, these medicated stents were still likely to occlude, so the patient was no better off. Now with the passage of time, the pendulum is swinging back to CABG surgery, because it is more cost-effective over the long term. Thus, although CABG surgery is very expensive, it has now been functionally "validated" from an economic perspective (although formal economic studies have not been concluded for all aspects of the aforementioned changes).

In our field, the transition from open Burch colposuspension, moving to laparoscopic colposuspension to allow early discharge with cost savings, then onto the tension-free vaginal tape (TVT) with its reusable instruments but equivalent if not better efficacy and cost savings, is analogous. In actual fact, a head-to-head cost comparison of laparoscopic colposuspension versus TVT has not been conducted. Nevertheless, with the advent of the TVT and transobturator procedures, it would seem that we have achieved the same cost savings but with a more robust cure rate, at least in the first 11–12 years of the TVT. Attempts to further "minimalize" bladder neck surgery with the recent "mini" procedures will certainly need long-term cost and efficacy data before their true value can be judged.

One of the major issues faced by the urogynecologists is the fact that the very companies who create and manufacture new surgical devices are the people we look to for funding of clinical trials of these products. Certainly, such companies are seriously interested in efficacy data (witness the withdrawal of the minimalistic" TVT secure device by Gynecare). However, surgical supply companies are not likely to conduct economic analyses for general publication. As business entrepreneurs, they must conduct market analysis and calculate what the market will bear, to thus determine whether they can realistically introduce a new product and still make an appropriate degree of profit. Similar practical constraints limit the ability of pharmaceutical companies to embark upon economic studies when introducing new drugs for incontinence. Nevertheless, government purchasing agents in many countries are now demanding some economic information in order to place new pharmacotherapies onto the government subsidy list (see later discussion regarding Markov models in this chapter [Figure 20.4]).

In order to make sense of what is going on economically, as each new product is introduced to the market (and some are discarded), the continence clinician needs to have a basic understanding of economic analysis in our field. This chapter will deal only with UI in women, in keeping with the subject of this textbook, and also because economic data about fecal incontinence and prolapse are very limited.

Also, because a formal survey of the economics of incontinence has recently been undertaken by a team of health economists and continence clinicians for the International Consultation of Incontinence [1], the present chapter gives a more clinically based summary of economic matters. The chapter is divided into two parts. Part One describes how to interpret an economic study, and Part Two outlines how to conduct an economic analysis. Throughout each part, important examples will be given from the literature, followed by a summary of important economic analyses from our field in the last decade.

PART ONE: HOW TO INTERPRET AN ECONOMIC STUDY IN THE CONTINENCE FIELD

Problem of Perspective

The perspective taken by any author in writing an economic analysis is fundamental to interpreting their analysis. For example, pharmaceutical companies often undertake *willingness to pay (WTP)* studies (see later for details of this method). They are most interested in knowing what patients will pay "out of pocket" for a new medication, which provides a certain theoretical degree of symptom relief. But *WTP* studies only consider the patients' perspective and their out-of-pocket expenses, with no calculation for the government subsidy provided for many drugs in many countries (see later for further discussion).

Surgical authors often look at the costs of a new procedure versus the old standard procedure, but if one looks at these reports critically, they often have a very short-term perspective, i.e., 6–12 months. We only have to remember the "honeymoon" success of the Stamey/Gittes/Raz procedures in the late 1980s, which soon gave way to large failure rates, to be reminded of this important axiom. One cannot stress strongly enough that at least 2 years and preferably 5 years of outcome and economic data should be looked at, before concluding that a new treatment is superior to the old one.

The final note of caution concerns economic models, such as the decision tree and the Markov model. Clinical (nonacademic) urogynecologists probably don't realize that an economist can design a Markov model to include whatever input parameters, success rates, procedural costs, etc., they wish. Now of course most economists would "fill in" the data in their model with published outcomes from the literature. The problem comes when there are no data to use!!! Economists may then make estimates for cure rates, complication rates, etc., and try to "plug in the numbers" into their model. This can have unfortunate consequences (see Section "Markov Models").

Different Types of Economic Studies Available: Cost of Illness versus "Economic Analysis" Studies

When reading an economic study, to start with, we need to consider whether one is looking at a cost of illness (COI) study or an analysis of the benefit of one treatment compared with another (hereafter called an economic analysis).

A COI study just simply tabulates all the costs of the incontinence being studied. Usually, these studies have three parts. First, they consider the *direct costs* of incontinence, which comprise the personal and treatment costs of the condition. The patient's perspective is usually taken first, for personal costs of incontinence products, laundry, barrier creams, etc. Then, the "payer" perspective is usually taken, for the costs of investigations and treatments. The payer is often a government body, except in the United States where a combination of Medicare/Medicaid and private insurance payers will be considered. Often, investigations and treatments involve some out-of-pocket "co-payment" from the patient (see Table 20.1 and Dowell et al. [2] for more detail).

Table 20.1 Direct Costs of Incontinence

Personal costs	Incontinence pads, disposable or reusable laundry costs for reusable products + urine-stained clothes/sheets Dry-cleaning of urine-stained clothes Replacement of urine-stained clothes Cleaning/replacing uriniferous carpets/furniture

	Barrier creams, Zinc ointment to prevent urine excoriation of the skin
	Bed pads, disposable or reusable
Treatment costs	Specialist visits (urogynecologists, urologist, geriatrician)
	Urodynamic tests, renal/postvoid ultrasounds
	Midstream urine cultures, other laboratory tests
	Pharmacotherapy costs
	Physiotherapy/NCA treatments
	Catheters for CISC
	Vaginal devices, e.g., dish pessaries and contiform
Surgical costs	Anesthetic costs/preop workup
	Surgeons' fees
	Theater fees
	Inpatient bed stay fees
	Post-op follow-up, treatment of complications

As can be seen in Table 20.1, the "payer" for this broad range of direct costs varies considerably, especially in the treatment section. For example, patients in a public hospital in most Commonwealth/European countries would seldom have any notion of operating theater fees, as the hospital budget is derived from the taxpayer revenue. However, most Americans would have a very clear notion of just how costly operating theater fees can be.

Another aspect of the *direct costs* of incontinence, which is not always considered, is the cost of the consequences of being incontinent. Part of the reason that these costs may be missed is that they are controversial. For example, the literature now contains several reports that incontinent people are 26% more likely to fall, and 34% more likely to sustain a fracture, than nonincontinent people [3]. This may occur because they are rushing to the toilet with urgency [4] or because they slip over when the urine renders the floor wet. However, this subject was initially quite controversial.

Even more controversial is the issue of whether incontinence can precipitate admission to a nursing home. The paper by Thom et al. [5] is frequently quoted to show that the risk of admission to a nursing home for an incontinent women age >65 is twice that of a nonincontinent woman, which of course has huge cost of implications. However, the actual study focused upon women who had either Parkinsonism, dementia, stroke, depression, or congestive heart failure, *with or without incontinence*. This would accord with clinical experience, i.e., UI in an otherwise *nonfrail* elderly woman who does not usually provoke nursing home admission, and it is the incontinence on top of the comorbidities that may provide the "final insult."

The top-down versus bottom-up approach to COI: Readers should be aware that many COI studies (and also economic models that are discussed in the next section) can compile their cost data in two ways. The *top-down* approach uses large national databases for costs (such as the Diagnostic-Related Groups [DRGs] in the United States/Australia or the Healthcare Resource Groups [HRGs] in the United Kingdom) combined with national prevalence data, to give an overall estimate of national expenditure for a particular condition. This is also known as *gross costing*. For example, see Hu et al. [6]. The alternative approach is to conduct individual, face-to-face enquiries about costs and utilization of resources in a sample of, say, 100 typical patients. This is known as the *bottom-up* approach, which is of course more accurate, but much more costly as a researcher has to actually interview all these patients about their incontinence costs in a systematic fashion (*for example, see* [7]). This method is also known as *microcosting*.

Second, the *indirect costs* of the condition are considered. These comprise costs arising from the individual losing productivity, e.g., time off work (and the cost implications for society). In the late 1990s, preliminary data began appearing regarding the impact of incontinence upon working women [8] including teachers and soldiers [9]. Between 21% and 33% of such working women suffered from incontinence. The effects upon their productivity included the loss of concentration, interference with job performance, need to take time from work for frequency of micturition, and the tendency to fluid restrict on the job. Nocturia with sleep disturbance leading to impaired daytime performance was also noted.

These results agree with large postal questionnaires from 2326 employed American women, [10] in which 37% had leaked urine generally in the past month. Severity (on Sandvik index) was slight 52%, moderate 40%, and severe 8%. The impact of incontinence upon ability to concentrate, performance of physical activities, self-confidence, and ability to complete tasks without interruption worsened with the severity of the leak (affecting nearly 75% of all those with severe leak status). Wu et al. [11] focused upon the work loss burden of women with overactive bladder (OAB). Absenteeism was 15% higher among 3077 OAB employees compared to 6154 controls. Multivariate analysis showed that OAB subjects had 4.4 more days off work than that of non-OAB subjects, yielding an excess cost of $1220 per OAB employee per annum.

Very recently, a specialized Work Productivity and Activity Questionnaire (WPAI) has been used in this type of research, which is broken down into sections about general health impact (WPAI-GH) and specific health disorders impact (WPAI-SH). Coyne et al. [12] studied 2323 adults with OAB symptoms versus 3472 adults with no or minimal OAB symptoms in 2012, using an Internet questionnaire format, with weighting of the respondents to reflect the general population. They found a highly significant impairment of work function in patients with OAB symptoms (see Figure 20.1). The rate of unemployment was doubled in men with OAB symptoms (not seen in women), and health-related unemployment was similar to that for asthma and rheumatoid arthritis.

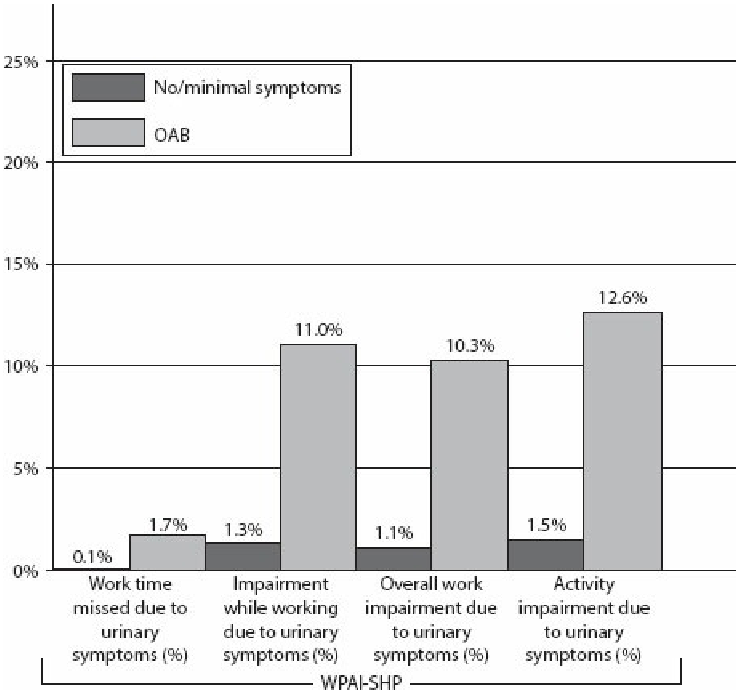

Figure 20.1 Percentage work impairment of overactive bladder patients WPAI-SHP, for women. (Reproduced with permission from Coyne KS et al., *Urology*, 80, 97, 2012.)

A further *indirect cost* of incontinence that is poorly measured to date is the cost of care provided by spouses and informal caregivers. Langa et al. [13] analyzed a large American dataset and estimated the yearly cost of informal continence care by relatives at US$ 6 billion (1998 dollars) or about $2000–$4000 per annum for women and men whose incontinence was severe enough to warrant using pads.

Third, a COI study should consider the *intangible costs* of the condition such as pain from urine excoriation or depression from the psychological impact of long-standing unpredictable incontinence. Urge incontinence is known to have a strong association with depressive symptoms [14] that occurs in 60% of those with idiopathic urge incontinence compared to 14% of those with pure stress incontinence, but the economic/cost–utility impact of this has not been studied.

Many COI studies have now been published regarding UI for most European and Commonwealth countries, for example, Sweden [15], Italy [16], France [17], the United States [18], and Australia [19].

COI studies are now considered somewhat “passé” within the field of health economics. Nevertheless, urogynecologists should be mindful that few COI studies have been published for prolapse treatments (see [1]). For a full description of the recent COI studies and economic analysis in the subject of fecal incontinence, see Moore et al. [1].

However, recently there have been two important COI studies published, which focus upon particular aspects of UI. Goren et al. evaluated the direct and indirect costs of patients with urge incontinence [20], to study the relative costs of patients who were undergoing treatments, (n = 481) compared with those who were untreated with prescription meds (n = 709). The authors used data from the 2011 U.S. National Health and Wellness Survey, which were an Internet-based questionnaire of a national sample of adults (total n = 75,000). The stratified random sample was checked to ensure that it was the representative of the corresponding adult U.S. population. Health-care utilization costs (e.g., doctor visits, emergency room visits) were precisely *costed*. Work productivity was assessed in employed subjects by a validated 6-item questionnaire that also noted activity impairment (the percentage of impairment in daily activities because of one's health in the last 7 days). Treatment users had *significantly* lower activity impairment (41% vs. 47%) but higher total direct costs ($27,290 vs. $21,490) (see Figure 20.2). Indirect costs did not differ between groups. The study was funded by Pfizer Inc.

Tapia et al. performed a meta-analysis of the literature [21] regarding the economic burden of UI in patients with neuropathic detrusor overactivity (DO), arising from multiple sclerosis (4 articles), spinal cord injury (4 studies), Parkinson's disease (2 articles), stroke (5 studies), and spina bifida (2 articles). They pointed out that neuropathic DO can result in severe uncontrolled urge incontinence, but the impact of this condition upon quality of life (QOL) and economic burden has not been well studied. The authors found that in all these neuropathic disorders, those who were incontinent had highly significant increased impairment of QOL than those who were not incontinent, but suffered from the same neurological disease. The economic burden of incontinence pad usage, diagnostic procedures, office visits, surgical procedures, urinary tract infection (UTI) costs, and fractures was several hundred dollars more per annum per patient with incontinence, compared to those with the neuropathic condition alone. The study was funded by Allergan.

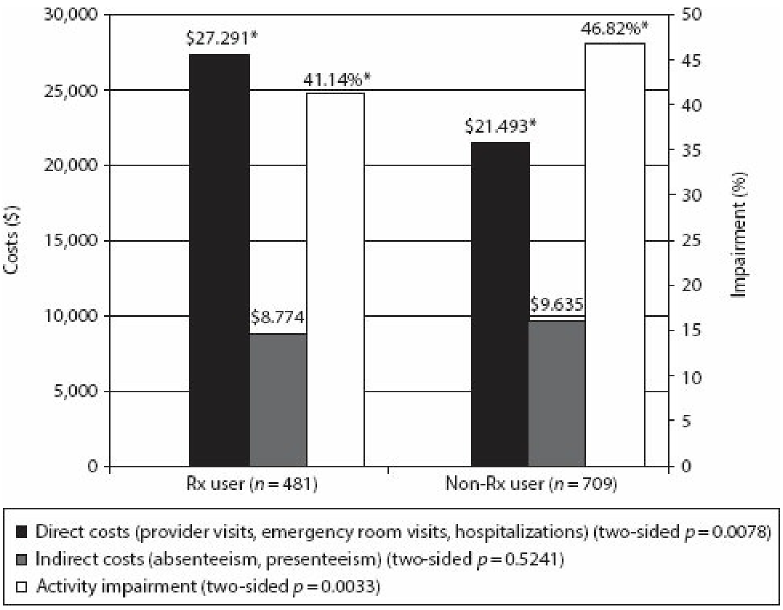

Figure 20.2 Direct and indirect costs of patient with urge incontinence, in the treatment users and treatment nonusers, with employed status*. Two-sided p-value < 0.05, for difference between treated and nontreated patients. (Reproduced with permission from Goren A et al., *Int J Clin Pract*, 68, 336, 2014.)

Formal Economic Analyses

As described, COI studies are not formal economic analyses because they simply summate the costs of the condition for a given population. Because the COI study does not measure the "value" of the treatments under study, it does not help clinicians decide how to allocate precious funds. In the following paragraphs, an overview of true economic analyses is given, with focus on the most desirable type, which is a cost-utility analysis (CUA). See Drummond et al. [22] for full review.

1. *Cost-minimization analysis* (*CMA*): In a CMA study, the costs of alternative health-care

strategies are compared, but we assume at the beginning of the study that the benefits of the two options are likely to be equivalent. When the two treatments actually prove to be equivalent in their outcomes, complications, and patient satisfaction, then a CMA is sufficient; the cheapest intervention is to be desired.

For example, our group undertook a randomized controlled trial (RCT) of the urogynecologists versus the nurse continence advisor (NCA), in the performance of conservative continence therapy for any mild to moderate incontinence. Nurses were able to give relevant prescriptions for anticholinergic drugs that the urogynecologists had written at the enrollment visit. We hypothesized that the outcomes for each clinician would be similar, which proved true. As might be expected, the nurses were a great deal cheaper despite the same result [23]. CMA studies are actually not that common in the literature.

2. *Cost–consequence analysis* (*CCA*): The CCA is a variation on CMA. It tests the hypothesis that a new treatment may result in a greater decrease in health-care utilization than a standard treatment. Unfortunately, whether the new treatment gives any benefit in outcome is not assessed, so CCA is not recommended.
3. *Cost–effectiveness analysis* (*CEA*): The term CEA covers a broad type of economic analyses wherein the effectiveness is measured by a general health outcome. One can perform a CEA with a narrow outcome such as a pad test, but you will miss other important effects. Therefore, we generally prefer the use of quality-adjusted life-years (QALYs) as the best health outcome measure for CEA. Once you include QALYs in your analysis, the study becomes known as a CUA. Other utility measures are also available, such as time trade-off or standard gamble (see the next section).
4. *CUA*: The CUA study is a type of CEA, wherein QALYs are generally used as the outcome measure, to compare two different treatments for the same condition. CUA is now considered to be the gold standard. QALYs capture all potential benefits of an intervention and allow comparisons with other health conditions, which is vitally important. The “bottom line” of both the CEA and the CUA are represented by the incremental cost–effectiveness ratio (ICER). The ICER represents the average cost of the intervention group minus the average cost of the control group. This amount is then divided by the average utility (QALY) of the intervention group minus the average utility (QALY) of the control group (see Section “Part Two: How to Conduct an Economic Analysis,” for full formula).
5. *Cost–benefit analysis* (*CBA*): Involves measuring the benefits in dollars (or other currency). When everything is measured in dollars, optimal choice can be found by addition and subtraction. However, it is difficult to measure the benefits in dollars, and many researchers, policymakers, and clinicians avoid placing a dollar value on life. CBA often uses a technique called WTP. This method involves giving a group of patients a questionnaire about how much money they would be willing to pay, from their own income, to achieve a given reduction in incontinence. For example, see [24].

> Imagine that a new drug, free of side-effects, against incontinence becomes available, that is not paid for by the state. This new drug reduces the number of times per day you need to go to the bathroom and number of urinary leakages per day by one quarter (25%); this means that if you, for instance, at present need to go to the bathroom 12 times per day and you have four urinary leakages per day, this will be reduced to nine bathroom visits and three urinary leakages per day. Would you choose to take this new drug if you, out of your income, have to pay 9 pounds per month [or 100 Swedish krona]?

The price can be varied up or down, and the leakage reduction is usually then varied up to 50% benefit.

The authors [24] found that the median amount patients were willing to pay ranged from 240 krona for 25% reduction to 470 krona for 50% reduction in symptoms. However, the authors noted that measuring WTP in the Swedish population is difficult, because health-care costs and the cost of pads are paid for by the state in Sweden, so patients will not have figured in these costs in their willingness to spend disposable income. Indeed, economists dislike WTP because such questionnaires survey people about their preferences and intents but do not observe actual behavior. WTP is similar to the standard gamble technique, which suffers from similar problems [25]. Thus, the preferred economic evaluation method remains the use of QALYs in CUA (using tests described later).

Test Instruments Suitable for Measuring Quality-Adjusted Life-Years

Instead of using theoretical questionnaires such as WTP, time trade-off, or standard gamble, there are several dedicated utility preference scores designed to measure QALYs, by directly questioning patients, before and after a given treatment. A utility score is a measure of patient preference for a given health state. The utility score is a standardized QOL test that summarizes the morbidity of a condition on a scale from 0 (death) to 1 (optimum health). Some scales allow patients to be so severely affected by the condition that they can give a score worse than death. Utility scores are combined with life expectancy to calculate QALYs, which can be used to quantify the benefits of any given treatment (or intervention).

EuroQol-5D: www.euroqol.org

The EQ-5D was developed by the EuroQol team from seven European countries [26,27]. It has 5 items measuring mobility, self-care, usual activities, pain/discomfort, and anxiety/depression. The upper boundary is 1.00, and the lower boundary is −0.59. This has become a popular instrument in clinical trials because it has been used in many languages and is very brief (five items).

For example, Tincello et al. [27] tested the relationship between stress incontinence and QOL, on the EQ-5D. The stress urinary incontinence (SUI) treatment study, a 12-month, prospective, observational, multicenter study in four European countries, evaluated the association of SUI symptoms with the EQ-5D among 3762 women seeking treatment. The EQ-5D scores were significantly and independently influenced by the comorbidities and by the total number of stress and urge incontinence episodes.

Assessment of Quality of Life AQoL

The AQoL comprises 15 items, 12 of which are used to compute the utility score. It includes 5 dimensions: illness (not used in utility calculations)-independent living, social relationships, physical senses, and psychological well-being [28]. The upper boundary is 1.00, and the lower boundary is −0.04.

15D

The 15D, created in Finland, has 15 items measuring mobility, vision, hearing, breathing, sleeping, eating, speech, elimination, usual activities, mental function, discomfort and symptoms, depression, distress, vitality, and sexual function [29]. The upper boundary is 1.00, and lower boundary is +0.11 (so a state worse than death is not allowed).

The 15D is a self-administered test of health-related quality of life (HRQOL) [29]. The single index score (15D score) on a 0–1 scale represents the overall HRQOL and is calculated based on population-based preference or utility weights. The 15D scores are shown to be highly reliable, sensitive, and responsive to change and valid for deriving QALYs. The 15D score is sensitive to UI in cross-sectional studies [30] and to change in incontinence severity following therapy [31].

Health Utility Index Mark 3: www.healthutilities.com

The health utility index (HUI) uses 12 items that measure 8 domains (vision, hearing, speech, ambulation, dexterity, emotion, cognition, and pain). The upper boundary is 1.00, and the lower boundary is −0.36. Harvie et al. have shown that the HUI Mark 3 (HUI-3) correlates well with other tests such as EQ-5D and the SF6-D [32].

SF-6D: www.qualitymetric.com

Whenever SF-36 raw scores are available, SF-6D utilities can be computed [33]. The SF-6D measures physical functioning, bodily pain, mental health, physical role, emotional role, social functioning, and vitality. The endpoints for the SF-6D are 1.00 and 0.30 for the worst possible health. Recently, the disease-specific King’s Health Questionnaire has been used for computation of QALYs also [34].

Decision Analysis: Economic Modeling

The aforementioned methods of economic analysis generally involve “real data,” e.g., that taken from a RCT or even a prospective observational study of one treatment versus the costs of “no intervention.” However, there are other forms of economic analysis that involve the construction of a theoretical model, that is then filled in with, or “populated”, from samples of data taken from the previous literature.

The two most common of these are the decision analysis, which involves making a decision tree, and a broader-based (more all-encompassing) Markov model. In both cases, the first step in the analysis is to identify the structure of the clinical problem, i.e., make a list of all the likely decision alternatives, all the clinical outcomes, and a sequence of events. Then, one assigns a mathematical probability to all chance events (e.g., 80% likelihood of cure, 2% likelihood of death). In step three, one assigns an outcome measure such as a QALY to all outcomes. In the fourth step, one performs the mathematical calculation of the expected utility for each strategy; this may reveal the preferred strategy. Finally, one has to test how “robust” the model is (how sensitive the outcomes would be to changes in the input parameters) by performing sensitivity analyses. A range of different inputs such as cure rates are changed, e.g., from 80% to 95%, to see if the model still holds true.

The *decision tree* is easy to understand. A group of patients with a certain type of incontinence enter into theoretical pathway along which they will undergo treatments and have a variety of outcomes. As they pass along the tree, various limbs of the tree branch off—each of these branches is called a “node.” A “decision node” is a branching off where the patient or the doctor makes a decision about what kind of treatment to have/administer. A “chance node” is a fork in the tree where a range of chance events occur that the patient or doctor may have little control over, such as “cure,” “partial response,” “nonresponse,” or complete failure (or they may encounter a complication, such as death, nursing home admission). The final event on the end of the branches of the tree is called the “terminal nodes.”

A recent example of a decision tree analysis in the field of UI was conducted in 2012. The authors constructed a decision tree model to compare medical costs and QOL associated with improved incontinence arising from treatment with percutaneous tibial nerve stimulation (PTNS) (12 sessions over 12 weeks) versus tolterodine extended-release (ER) tablets [35]. Figure 20.3 shows the decision node (square box) where patients have either PTNS or tolterodine for 3 months. Moving along to the right on the diagram, the first chance node yields options of “response” or “no response.” The next chance node concerns side effects, which may or may not cause the patient to stop the treatment. Final options are improvement or persistent symptoms.

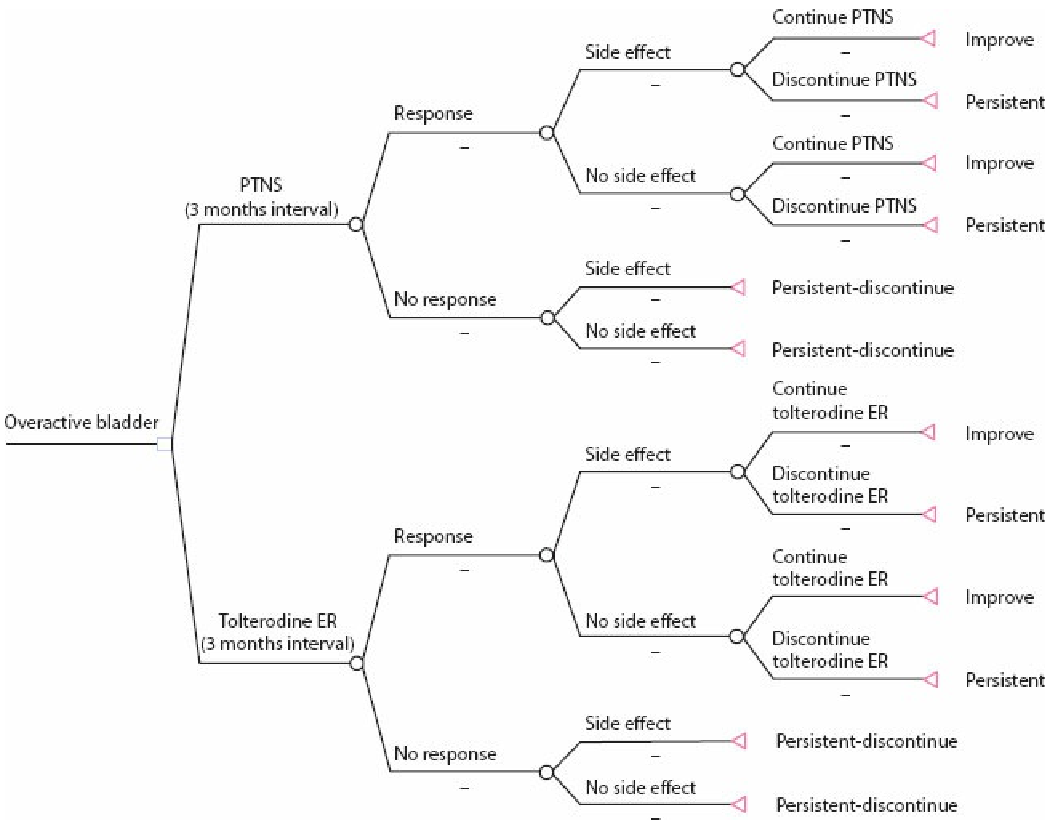

Figure 20.3 Decision tree analysis comparing percutaneous tibial nerve stimulation versus tolterodine

extended-release model runs over a 3-month interval (analyzed over 12 months, 4 cycles). (Reproduced with permission from Chen HW et al., *J Urol*, 187, 178, 2012.)

In the model, the likelihood of symptom improvement was 79% for PTNS at 3 months and 56% for tolterodine, based on a published RCT [36]. The likelihood that patients would continue therapy was 75% and 63%, respectively, from the literature. Side effect probability was 21% and 31%, respectively, although PTNS side effects were estimated (actual published side effects of PTNS are 3%–16%).

The cost analysis was from a societal perspective, based on direct medical costs (no indirect or intangible costs). The 1-year cost of PTNS was $43,754 per patient, versus $13,400 for tolterodine, taken from U.S. Medicare codes. The PTNS cost per session was $203, which seems a high cost. The tolterodine cost was $150 per month, clearly based on the costs in the United States and not applicable to Europe, the United Kingdom, or Australasia. Personal incontinence costs were taken from Subak et al. [37].

The QALY value for improved UI was 0.92 versus 0.73 for persistent incontinence. These values were taken from the time trade-off questionnaire [38], in which 40 women with a variety of OAB symptoms were asked to evaluate a range of clinical scenarios. Thus, the QALY scores were estimated from a study of patients who had not undergone either of these treatments.

A *Markov model* is slightly superior to a decision tree because it allows the dimension of time to come into the analysis. The decision tree, as shown earlier, assumes that the chance of particular events such as cure/partial cure/failure is stable over time. However, we know only too well that UI treatments may "look good" immediately after they are given (new drugs or surgery) but often begin to fail over the longer term. The receptor for the drug may become "resistant," or the surgical sutures may dissolve/become remodeled.

Markov models are set up to allow one to incorporate such changes over time. Patients can go through various cycles of moving from one treatment state to another, over time. The likelihood of moving from one state to another is given a mathematical probability (using techniques derived from matrix algebra). The final option is to become dead, a state from which the patient cannot move.

The author of the Markov model needs to define health states and the probability of moving from one to another, as in the decision tree. But also, the author determines the cycle length or time period over which one moves between states, e.g., weeks to months for pharmacotherapy and months to years for surgical studies. The outcome measure used to determine treatment effect is generally the QALY.

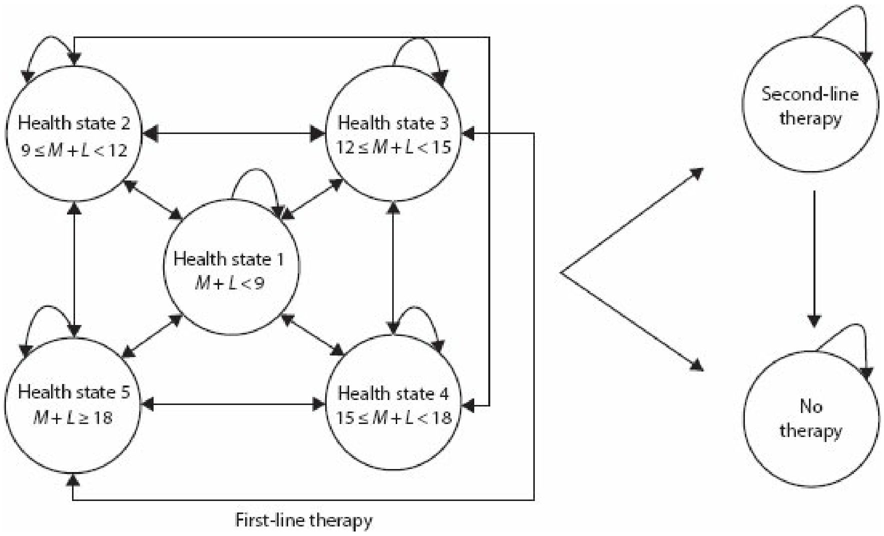

Figure 20.4 A Markov model comprising six health states, used to analyze solifenacin 5 mg/day versus oxybutynin 5 mg TDS, over 1 year. (Reproduced with permission from Hart, W.M. et al., *J. Med. Econ.*, 16, 1246, 2013.)

A recently published Markov model [39] compares the cost-effectiveness of solifenacin 5 mg/day versus oxybutynin 5 mg three times daily [39], based on the data obtained from the VECTOR RCT [40]. The cycle length was 1-month duration, repeated 12 times in the analysis. As shown in Figure

20.4, patients could move between five health states, dictated by their summated numbers of micturitions and leakages per day. Health State 1 (less than 9 micturitions or leaks per day) was considered “mild,” whereas Health State 5 (more than 18 micturitions or leaks per day) was considered “severe.” After 2 months of treatment, patients were assumed either to move to second-line therapy (tolterodine, 65% of cases) or to drop out from anticholinergic therapy (35% of cases), based upon published literature.

The costs were tallied from pad-usage data taken from the STAR study [41] and from GP visit costs in the United Kingdom. Utility values were taken from published data for patients using these medicines [42]. The annual costs of oxybutynin (£364) were lower than that of solifenacin (£504), but pad costs were higher for oxybutynin (40% of total) than for solifenacin (22% of total). The difference in QALYs between drugs was small (0.011, in favor of solifenacin).

PART TWO: HOW TO CONDUCT AN ECONOMIC ANALYSIS AND WHAT HAVE WE LEARNED FROM ANALYSES IN THE LAST TWO DECADES

How to Conduct a Cost-Utility Analysis

Clearly, the CUA is now the gold standard in economic analyses. The following paragraphs explain ten key points that must be included in a CUA—a “how to do it” guide to achieving the appropriate minimum standard for performing and reporting CUAs. Each point should be explicitly covered in every study [1].

1. The *research question, i.e., the hypothesis that treatment A will be more effective per unit of QALY than treatment B*, must be clearly stated. All CUAs must compare at least two different therapies. One of these should comprise the current standard practice. For example, when comparing surgeries for stress incontinence, one of the comparators should be a long-standing method; avoid comparing two new methods side by side.
2. The *Time Frame over which costs and benefits are measured should be long enough to capture the economic impact of an intervention* and all relevant future health outcomes such as treatment failure or complications. Pharmacology studies of 12-week duration give very little real economic information, and surgical complications/failures seldom emerge in less than 1–2 years.
3. *The perspective used by the author must be clearly stated.* Total society perspective (all payers) is the optimum (“gold standard”). Other perspectives, such as the payer or the patient’s out-of-pocket expenses, may be useful but must be stated clearly.

   When reading an economic analysis of continence treatments, usually comparing an older standard therapy with something new, one must be very careful. The writer may inadvertently have used a narrow perspective, for example, just looking at the treatment costs from the hospital provider perspective as regards savings in bed days or theater consumables.
4. *Probabilities* are needed for each “chance” event, if you are constructing a Markov model or a decision tree (i.e., chance of cure or chance of an adverse event). These should come from meta-analyses of RCTs (or from individual clinical trials if no meta-analysis).
5. *Costs* should be described in detail, including exactly how the “charges,” “bills,” or co-payments were derived. The year of the cost data should be given because studies are often not published until months or years after the data were actually collected.
6. *Outcome measure*: Measures of effectiveness depend on the type and objectives of analysis. QALYs are the gold standard, as described previously in this chapter.
7. *Analytic model*: If a real clinical study is not being used, but a Markov model or decision tree is being constructed, each intervention must be described and possible courses of events identified, including the expected course of disease, treatments, complications, and outcomes.
8. *Discounting*: Since the value of both costs and benefits may decrease over time, discounting is used to calculate the present value of money and health states that will occur in the future. Future costs and utilities should be discounted to present value; 3% per year is a recommended starting point.
9. *Incremental analysis*: The purpose of a CUA is to describe the relative value of one health-care strategy compared to another. An *ICER* is the incremental cost divided by the incremental effectiveness of intervention a compared to intervention b and is calculated as follows:

Averages should be used (*not* medians) because we want to see the effect of statistical outliers. The "leverage" or impact, of the outliers, should then be tested in a sensitivity analysis.

ICER= Average Costintervention a− Average Costintervention bAverage Utilityintervention a
−Average Utilityintervention b

10. *Sensitivity analysis*: A sensitivity analysis should allow the reader to understand whether the conclusion of the analysis would hold true if either the costs or the probabilities (of cure or complications) were to vary substantially. For example, if one treatment costs EUR€5000 and has a cure rate of 90% and the second treatment costs €2000 with a cure rate of 80%, then the ICER will assess whether the resultant benefit in QALY/QOL makes the first treatment worthwhile. The author should then vary the costs and the cure rates in the model to see how much variation in real life would be allowed for the conclusion to remain valid.

What Have We Learned from Economic Analyses in the Recent Past?

This overview of our current state of knowledge about incontinence costs is organized according to the type of incontinence (stress, urge, or mixed). Conservative treatments will be considered followed by surgical treatments.

Stress Incontinence: Conservative Therapy

There have been surprisingly little economic data generated about conservative treatment for stress incontinence. Neuman et al. [43] calculated the physiotherapy treatment costs for 274 women with stress incontinence in Australia. A median of 5 (Interquartile Range [IQR] 4–6) treatments were given, for a median cost of $250 (IQR 206–295) in 2005. Of the patients who completed the therapy, 84% were dry on stress test. Improvement was seen on the King's Health Questionnaire, but utilities were not collected (nor calculated as they could have been). Monz et al. [44] studied the total costs of physiotherapy treatment in France, Germany, Spain, Sweden, and the United Kingdom. These ranged from €64 to €467 (for a range of 4–10 prescribed visits).

As regards conservative therapy for mixed incontinence, Williams et al. [45], of the Leicestershire UK MRC Incontinence Study Team, undertook a large RCT of conservative therapy in 2005. Personal and treatment costs were measured (year 2001). A sample of 3746 men and women were randomized in a 4:1 ratio either to treatment by a specialist NCA (who provided conservative therapy and urodynamic testing) or to routine continence care by their GP and local continence nurse. Cure at 6 months occurred in 28% versus 19% (95% CI: 5–13, $p < 0.001$). The intervention costs at 6 months (£252, IQR 234–268) were greater than the routine costs (£73, IQR 53–93). Cost utilities were not collected.

Subak et al. [46] performed a *bottom-up* analysis of the personal "routine care" costs (pads and laundry questionnaire) of incontinence in 293 women age over 40 who had stress or urge leak more than 3 times per week, wanted help, but had not been treated in the previous 3 months. QOL was tested by the HUI-3 and WTP. Women were willing to pay $70 per month for 100% reduction in the frequency of incontinence. WTP increased 2.3-fold in the highest income bracket compared to the lowest. WTP for improvement exceeded the routine care costs by three- to sevenfold. On univariate analysis, women with daily incontinence had a 10% lower mean score on the HUI-3 compared to those with only weekly incontinence episodes (0.81 versus 0.90, $p = 0.02$). The scores of women with urge leak were 6% worse than those with stress leak.

Pinto et al. [47] studied the effect of weight loss on QOL in obese women with UI. QALY tests, which had not previously been used to measure response to incontinence treatments, were employed (the HUI-3, the SF-6D, and the estimated Quality of Well Being [e QWB]). In this RCT, 338 women who had at least 10 leakage episodes per week and a BMI of 25–50 were randomized to either a behavioral weight loss program (weekly small group sessions over 6 months, then fortnightly over 12 months) comprising a 1200–1800 cal/day diet, with regular physical activity, versus control (seven 1-hour group education sessions over 15 months). Weight loss at 6 months was 8% versus 1.6%, respectively ($p < 0.001$). At 8 months, difference was 5.5% versus 1.6% ($p < 0.001$). Reduction in incontinence episodes was significant at 6 months (−47% vs. −28%) but not at 18 months (−62% vs. −55%). Only basic incontinence management information was given.

The changes in HUI-3, SF-6D, or e QWB did not differ between active therapy and control, but for all participants, weight loss was directly correlated with benefit on the e QWB but not for the HUI-3 or SF-6D. Surprisingly, reduced UI did not correlate with improvement in these three QALYs.

Recently, Sjöström et al. [48], from Sweden, compared the treatment costs and QALY changes of 250 stress incontinent women enrolled in a RCT of 3 months of pelvic floor muscle training via an Internet-based program (that included continuous e-mail support from a physiotherapist) versus a training program sent in the post, versus no treatment. Costs were evaluated from a 1-year societal perspective, including all the staffing costs of the Internet program and all the patients' personal costs. The ICER for Internet treatment versus postal treatment was EU€21,797 per QALY, which is considered highly cost-effective.

In 2012, Albers-Heitner et al. [49], from the Netherlands, performed an economic evaluation of a RCT of the treatment for stress or mixed incontinence in 186 patients, who had therapy by a NCA, versus 198 subjects who had usual care by a GP in the Netherlands, using the EQ-5D to measure QALYs. Personal and indirect costs (but not intangible costs) were assessed at 1 year. Compared to usual care, the NCA treatment cost EU€16,740 per QALY gained, which was significantly more cost-effective than the usual care. The threshold for cost-effective therapy in the Netherlands (EU€40,000 per QALY gained) was justified by the use of NCA intervention. This publication is an excellent example of the incorporation of economic analysis into a RCT.

Ho et al. [50] performed a *bottom-up* study of the short- and long-term direct costs of conservative and surgical management of childbirth-related stress/mixed UI in 150 women. During the initial treatment, patients with stress UI treated conservatively incurred a median direct cost of AUD$658 per capita (IQR 476–$1191) compared to $6870 per capita for surgical treatment (IQR 6320–$7508). Similar cost difference was seen for the two treatments for mixed incontinence. Of regular clinic attendees, 39% of conservatively treated and 78% of surgically treated patients were cured. QALYs were not measured. At 6–13 years follow-up, 52% responded to a postal questionnaire, of whom 46% remained cured. The median treatment cost for the total group of postnatal incontinence (irrespective of continence status) was AUD$885 per capita per annum (IQR 338–$2589).

Before moving on to the cost-effectiveness of surgical treatments, a few words about *vaginal devices* are needed. Although a range of such continence devices have been manufactured (such as the Contigard vaginal sponge, Introl bladder neck support device, Femassist urethral occlusive device, Contiform vaginal ring, and continence dish), economic analyses of these are uncommon. However, a good lesson about the importance of such economic testing can be learned from the story of the Femassist device.

When it was first launched, the Femassist device was estimated to cost AUD$12.50 (in 1997, then about EUD€8) and was to be changed weekly by the patient. The staff from our unit developed an incontinence cost index [2] and then measured incontinence costs before and after using the Femassist [51]. The median person costs fell from AUD$6.52 per week (IQR 1.5–$10.6) down to a median of 1.57 per week (IQR 0.84–$4.89). Thus, the savings provided by the device in this group of 100 women with moderate leakage on pad test (typical of those who might want to use it) was not equivalent to the cost of the device. Unfortunately, the production of the device ceased about 10 years later.

Surgery for Stress Incontinence

Cody et al. [52] performed a systematic review of the cost-effectiveness of TVT versus open colposuspension. Such older studies remain as they are good examples of appropriate methodology. Using a Markov model, the TVT dominated the open colposuspension (lower costs with similar QALYS) within 5 years. The authors pointed out that there were no RCT data beyond 2 years however. Wu et al. [53] also developed a Markov model to compare TVT versus open colposuspension at 10 years, with similar findings but with a similar proviso that no long-term data exist. Much of the economic data used in the Markov models arose from the now-famous RCT of Manca et al. [54], which compared TVT to open colposuspension at 6 months. Procedural and convalescence resource costs were collected directly from the 344 trial participants, and then health-care consumption was estimated from the British NHS data, along with QALYS (on the EQ-5D). The TVT saved GBP£243 per patient and gave slightly higher QALY benefits (0.01 units per QALY). Dumville et al. [55] compared laparoscopic versus open colposuspension as part of a RCT. The analysis of costs and QALYS (on EQ-5D) at 6 months revealed a mean increase of £372 for the laparoscopic procedure, but a QALY benefit of 0.005, yielding an ICER of £74,4000 at 6 months for the benefit of the laparoscopic colposuspension. This

ICER falls below the recommended National Institute for Health and Care Excellence (NICE) guidelines for cost-effective therapy (£30,000 per QALY gained) (www.nice.org.uk).

In 2011, Lier and colleagues [56] performed a within trial CUA in a randomized trial of transobturator tape (TOT) compared with TVT among 194 women in Canada. The cure was assessed by objective pad tests. They assessed costs in 2007 Canadian dollars from the public payer's perspective, i.e., CAD$807 for surgical kits, plus day-only surgical costs, and 12 months of care costs. The 15D utility instrument was used to measure QALYs. At 1-year postsurgery, 81% of patients with TOT were dry on 24 hour pad test versus 77% of patients with TVT; 15% of the patients with TOT had groin pain (versus 6% of those with TVT), but whether this contributed to medical costs over 12 months was not clear. The TOT group had a nonsignificant average saving of $1133 (95% CI: −2793; 442), or 17%, with no difference in average QALYs between groups (95% CI: −0.02; 0.01). TOT was cost saving in over 80% of sensitivity analyses, suggesting that TOT would be cost-effective compared with TVT in the treatment of SUI. These results agreed with a Markov model (derived from Medicare data in the United States and published QALY data), which compared retropubic midurethral slings versus transobturator slings, over a 1-year period [57].

However, longer-term assessment of clinical and economic outcomes is needed to confirm this finding.

Recently, Subak et al. [58] have studied the out-of-pocket costs after Burch colposuspension or a fascial sling at 2 years, based upon the study of Subak et al. [37]. These patients were quite wet, with baseline 23 leaks per week. After surgery, both groups combined leaks per week fell by 86%. Pretreatment personal costs (US$16.6, ± $27) fell by 72% to US$ median $0.10, IQR 0–$3.39. Continence surgery was associated with improved disease-specific QOL scores, but QALYs were not measured.

Also, Richardson et al. [59] have evaluated the cos–effectiveness of a midurethal sling (MUS) at the time of abdominosacrocolpopexy for the prevention of occult stress incontinence. Only direct costs, obtained from Medicare payments, were included (no indirect or intangible costs were considered). Other options include the following: (1) only performing the MUS if stress incontinence was found postoperatively or (2) only performing the MUS if preoperative urodynamics revealed occult stress incontinence.

Based on the published literature, the QALY score for stress incontinence was 0.71, for those with no stress incontinence QALY = 0.93. The decision trees analysis at 12 months showed that the ICER for combined abdominosacrocolpopexy with midurethral sling (US$2,867 per QALY) was the most cost-effective approach. In the United States, an ICER of US$50,000 per QALY gained is considered cost-effective.

Urge Incontinence

As regards *conservative therapy of urge incontinence*, there have been no cost–effectiveness studies of first-line therapy and bladder retraining. However, many "economic studies" of pharmacotherapy have been undertaken, although most are funded by the relevant pharmaceutical company.

The Food and Drug Administration of the United States does not evaluate economic data when looking at a new drug, but insurance companies or government purchasers often require such data. In the United Kingdom, the NICE does require economic review; they have withheld approval for new drugs that have an ICER greater than £30,000 per QALY.

One of the few independently funded studies [60] performed economic evaluation of five antimuscarinic drugs (both immediate-release [IR] "usual" form and ER forms) for the treatment of OAB. They compared oxybutynin, oxybutynin ER, transdermal oxybutynin, tolterodine, tolterodine ER, trospium, solifenacin, and darifenacin. Solifenacin had the lowest costs and greatest effectiveness for OAB. However, their analysis did not comply with the 10 steps recommended for CEA (see page x). The perspective was that of the payer (rather than a societal perspective), the time frame was too short (3 months) and complete continence was the main effectiveness measure (rather than QALYs).

The *UTIN group* [61] is currently conducting a clinical trial comparing behavioral treatments to medications for urge incontinence. This important study will measure costs and utilities. Through a NIH-funded substudy, separate researchers will conduct parallel economic evaluation of this trial. Recruitment was completed in the late 2013, data not yet published.

Solifenacin studies: Milsom et al. [62] performed a CEA of solifenacin (5–10 mg) versus tolterodine

4 mg sustained release, based upon the STAR RCT [41] and 2 other RCTs of solifenacin versus tolterodine and placebo. QALYs were not included in the original trials, but the EQ-5D was estimated from original HRQOL data collected in 1997. The cost differences between solifenacin and tolterodine ranged from €6 to €127. The authors concluded that flexible-dose solifenacin was more cost-effective than tolterodine 4 mg. This study was supported by Astellas.

Herschorn et al. [42] undertook a Markov model based upon the VECTOR study, which compared solifenacin 5 mg/day versus oxybutynin 15 mg/day in Canada. The withdrawal rate due to side effects of oxybutynin (19%) was much greater than that for solifenacin (3%). No QALY data were included in the original VECTOR study. Their 8-week efficacy data were projected over 1 year, which is an arguable model. Solifenacin yielded a cost saving of CAD$1,830 per annum, giving an ICER of CAD$14,000. This study was funded by Astellas.

Cardozo et al. [63] performed a decision tree analysis of solifenacin versus fesoterodine, oxybutynin ER, propiverine, and tolterodine ER and IR in the United Kingdom. In this 1-year model, success was individually defined for frequency, urgency, and urge incontinence. The model assumed if the patient had no success on a drug that was only available in one dose, then the patient was given no further treatment. The original study did not include QALY data, which were calculated from WTP data published by Kobelt et al. [64]. Because oxybutynin was so much cheaper than the other drugs (20% of total costs versus 60%–70% of total costs for the other therapies), oxybutynin was dominant for 2 of the 3 outcomes.

Darifenacin: Short-term efficacy (12 weeks) and longer-term effects (24 and 52 weeks) of darifenacin have been evaluated [65,66]. Abrams et al. [65] found that darifenacin was associated with significant improvements in QOL as measured by the King's Health Questionnaire at 12 weeks relative to placebo. Chancellor et al. [66] found that darifenacin and darifenacin combined with a behavioral modification plan both resulted in improvements in symptoms and QOL, as measured by the Overactive Bladder Questionnaire (OAB-q), but there were no differences between the two groups. Unfortunately, neither study measured utilities.

Tolterodine: Burgio et al. (the UTIN group) studied 10 weeks of open-label, tolterodine ER alone ($n = 153$) or combined with behavioral training ($n = 154$). The aim was to allow discontinuation of therapy, with follow-up at 8 months [67]. The rate of successful discontinuation of therapy at 8 months was the same in the combination therapy versus drug therapy alone groups (41% in both groups). However, more patients who received combination therapy (versus drug therapy alone) achieved a 70% greater reduction in leakage at 10 weeks (69% vs. 80%; 11% difference [CI: −0.3% to 22.1%]). Women in the combination therapy group had greater benefit on the UDI and the OAB-q (both $p < 0.001$). The addition of behavioral training to drug therapy did reduce incontinence frequency during active treatment. However, it did not improve the ability to discontinue drug therapy (yet maintain improvement in continence status). This finding is counterintuitive to clinical practice.

Two studies evaluating the cost–effectiveness of tolterodine versus PTNS have been published. In 2009, Robinson et al. [68] performed a cost-minimization study of PTNS versus tolterodine ER 4mg, involving 1–2 year follow-up, from the perspective of the NHS. The model assumed that the two treatments had equivalent efficacy (based on unpublished data). Adverse effects were considered to be cost neutral. The patients having tolterodine were followed for 2 years; the duration of follow-up for PTNS was not clearly stated. Tolterodine appeared to be the cheaper treatment but alteration of the variables in the model had a large effect. The report of Chen et al. [35] has already been discussed under decision tree analysis.

Studies of multiple antimuscarinic agents: Nilsson et al. [69] performed a decision tree analysis of anticholinergic medicines available in Sweden. The costs of medicines and incontinence pads were carefully costed from national data. The costs of doctor visits were not included. QALY data were transformed from the King's Health Questionnaire results, obtained from the pooled data of two RCTs regarding fesoterodine (as per standard method discussed). The overall framework was to compare an older drug (oxybutynin IR) with the newer drugs as a group (tolterodine, solifenacin, fesoterodine, darifenacin, and oxybutynin patch), including continuation rates over 1 year from the national drug register. The option of "no treatment" was also included.

The Markov model was carefully constructed and closely resembles the standard clinical practice. The results show that treatment with the newer drugs cost EUR€301 more per annum versus no treatment, but the average gain in QALY (0.046) was substantial. The cost per QALY gained by treatment with newer drugs versus oxybutynin was €37,119, which remains cost-effective. A full range of sensitivity analyses were conducted. No pharmaceutical company was a sponsor of this study.

Also in 2012, Armstrong et al. [70] performed a decision tree analysis of 11 different anticholinergic medicines, using 11 published reports of patients with “OAB-wet.” The primary outcome was cost per treatment success (defined as no incontinence episode for 3–7 consecutive days).

Costs for pads were not included but costs of comorbidities such as UTI, skin infections, bone fractures, and depression were obtained from the U.S. literature. Medication costs were carefully tabulated, ranging from oxybutynin 5 mg BD (US$37 per 3 months) to oxybutynin transdermal patch 3× per week (US$545 per 3 months). Solifenacin 5 mg daily costs US$459 per 3 months. These figures may be quite different in other countries. Cost utility was derived from WTP studies that were not referenced. Using “cost per additional continent patient,” the ICER of solifenacin dominated oxybutynin 5 mg BD by $1,338 per annum. Sensitivity analyses were conducted. The senior author was an employee of Astellas.

Surgery for Urge Incontinence

Studies regarding botulinum toxin type A (Botox A) injections: Three studies comparing Botox A with other current treatments have been performed. Wu et al. performed a Markov model analysis of Botox A versus anticholinergic medication [71], over 2 years, assuming that only 33% of patients would comply with anticholinergic therapy over this time. The Botox treatment cycles were more expensive (US$4,400) than the anticholinergic medication (US$2,560), but the Botox was more effective (QALY gain 1.63 versus 1.50), yielding an ICER of $14,377.

Wefer et al. from Germany evaluated Botox A injections in 214 patients with neuropathic DO [72]. A total of 300 IU of Botox were injected on an inpatient basis (which is common practice in neuropathic DO but varies from some clinical practice in idiopathic DO). Pad costs were reduced from EUR€2.11 per day to €1.05, and medications for UTI fell by half (from €162 per annum to €80 per annum). No QALY measurements were performed.

Robinson et al. [73] undertook a Markov model study comparing Botox with PTNS over 2 years in refractory idiopathic DO. Repeat Botox injections were assumed to occur every 8 months; 20% of patients were assumed to perform clean intermittent self-catheterization (CISC) for 4 months. QALY data were taken from the literature. PTNS was cheaper than Botox (GBP£1,700 versus £4,067) and had a lower ICER (£50,133 versus £111,953) but neither would satisfy UK NICE guidelines for cost–effectiveness (i.e., not less than £30,000 per QALY).

Sacral nerve stimulation (SNS): SNS is a second-line treatment for refractory OAB. Five recent papers present different aspects of cost analysis and cost–effectiveness of SNS.

Aboseif et al. [74] retrospectively reviewed the costs related to SNS 1 year from pre- to postimplantation in the United States. In a heterogeneous group of patients (including retention and chronic pelvic pain), SNS treatment reduced 92% of outpatient visits and diagnostic/therapeutic procedure costs, along with a 30% reduction in drug costs. The costs of the neuromodulation implant itself, nor the surgical implantation costs, were not included. QALYs were not ascertained.

A large multicenter cohort study in France [75] evaluated the costs of 190 OAB-wet patients and neuropathic DO, as well as another 85 patients with OAB-wet plus fecal incontinence (double incontinence). Treatment costs included insertion of preliminary tined leads under GA as an outpatient, then permanent implant as an inpatient. Inpatient Botox injections were the comparator, but patients having routine care were also compared. Travel costs were also included, which extended for 2 years after the SNS implant procedure.

The median overall cost per OAB-wet patient (for 2 years of SNS) was EUR€16,403. This was on average €8,525 more per patient, compared to those on alternative treatments. These comprised conservative measures (medication and diapers/pads), botulinum toxin injection, enterocystoplasty, or urinary diversion. Devices and hospital stays accounted for 40% and 52% of the total cost, respectively. Although a limited CEA was performed over 2 years, the interpretation of the results is difficult because of the heterogeneity of the study population and surgical procedures and the lack of clear descriptions of the cost–effectiveness parameters. Their data suggest that SNS for OAB-wet is not cost–effective over a 2-year period. This is in agreement with the data from Siddiqui et al. [76], and not surprising since the initial device costs are very high. Interestingly, their data suggest that SNS may be cost-effective even in the short term for patients with double incontinence [75].

Siddiqui et al. [76] performed a CEA of SNS vs. intravesical Botox A in patients with idiopathic "OAB-wet" in the United States over 2 years. Interventions comprised a staged implant procedure for SNS using a tined lead and office injections of 200 units of botulinum toxin A. For the SNS strategy, no information about the procedures was provided (local vs. general anesthesia; outpatient vs. inpatient clinic). Based upon their Markov model, the base case SNS treatment was more expensive ($15,743 vs. $4,392) but also more effective (1.73 vs. 1.63 QALYs) than botulinum toxin A. During the 2-year period, SNS was not cost-effective with an ICER of $116,427 [76]. This study reiterates the notion that CEA over just 2 years for a costly implant device is open to question.

Two cost–effectiveness studies have considered the longer term, comparing SNS and botulinum toxin A in the Netherlands [77] and Spain [78]. In the Netherlands, Leong et al. [77] showed that SNS becomes cost-effective from the fourth year postimplant on, given an ICER threshold of €40,000/QALY [77]. These data are based upon two procedures under general anesthesia: (1) a staged SNS procedure involving a tined lead test phase in the operating theater on an outpatient basis, followed by an inpatient stay for device implant and (2) inpatient stay for botulinum toxin A injection in the operating theater.

The Dutch study is in keeping with the Spanish study by Arlandis et al. [78] that showed SNS to be cost-effective from 5 years postimplant onward (using an ICER threshold of €30,000/QALY). These results are based on (1) a staged SNS procedure involving a tined lead test phase and (2) 100 units of botulinum toxin A. No further data were provided on the procedure (inpatient vs. outpatient; local vs. general anesthesia). In both studies [77,78], several assumptions had to be made due to the lack of long-term data beyond 1 year for botulinum toxin A injections and 5 years for SNS therapy, such as therapy transition rates after failure and dropout rates. To what extent these assumptions are valid is unknown.

Because there is no standard protocol of botulinum toxin A injection, a different protocol using 200 units every 14 months was evaluated in the Arlandis study [78], which proved cost-effective on the ICER < €30,000/QALY threshold.

Furthermore, both studies quote a 1-year success rate for SNS of 90%, based upon Van Voskuilen et al. [79] that describes the effect of SNS in 39 patients with OAB over 15.5 months follow-up. However, in that study 10 patients were lost to follow and were excluded from the analysis. Therefore, the 90% success rate may be an overestimation. In the worst case scenario (considering ten lost-to-follow-up patients as failures), both studies would give a 61% success rate. This would obviously influence the cost–effectiveness evaluation. A similar consideration applies to the 5 years success rate of 70%, based upon Van Kerrebroeck et al. [80], which considers patients lost to follow up as last observation carried forward.

Sensitivity analyses for several parameters estimated by expert opinion have been performed. In the Netherlands, SNS remained cost-effective over a 5-year period (ICER < €40,000/QALY) when the estimated dropout rate of 4.3% for both treatments was changed to 2% or 6% and when utility value for incontinence was changed from 0.73 to 0.80. SNS was no longer cost-effective over 5 years in the following cases: (1) if botulinum toxin injections is done under local anesthesia (common practice in several countries), (2) if the peripheral nerve evaluation (PNE) test for SNS screening is used (because of the lower success rate of 55% for PNE compared to 75% for tined lead screening), (3) if bilateral testing is done, and (4) if the new and smaller stimulator (Interstim II) is used.

For a full and detailed review of all direct costs (personal and treatment, including all of the earlier therapies) along with indirect and intangible costs of urge incontinence, readers are recommended to the recent publication by Coyne et al. [81].

SUMMARY AND CONCLUSIONS

Looking at the past three decades of economic studies for UI, we have certainly come a long way. Twenty-five years ago, we were still trying to establish the basic COI in a range of countries and health-care models. In the last 15 years, more continence clinicians have collaborated with health economists. We are now seeing formal economic analyses of the important questions in this field.

Twenty-five years ago, doctors essentially controlled the health-care budget. As long as we could show efficacy and safety, the treatment was usually implemented.

As government bodies such as NICE (and the American insurance companies/health maintenance organizations) gain ever more control of the outflow of monies to patients and health services, we need to generate economic data to show that a new treatment is not just more *effective*, but is more *cost-*

effective, than the old standard. If we clinicians don't generate the raw data, then the health economists will create *top-down* economic simulations such as decision trees or Markov models, to be used instead of real economic data from RCTs. If the conclusions drawn from such theoretical models don't mirror real-life data, we have only ourselves to blame for the lack of true economic data, and for the health policies that may be derived from these mathematical models.

NOTE REGARDING: PROLAPSE

Unfortunately, to date there does not appear to be a QOL test that is sensitive to change after treatment for prolapse. Therefore, economic analyses does not appear to be feasible for prolapse treatments. However, the recent chapters on prolapse, and economic analyses, in the 5th International Consultation on Incontinence [1,82], contain a summary of COI and cost-minimization studies for prolapse (pp. 1853–1854 and pp. 1429–1430, respectively).

ACKNOWLEDGMENTS

I thank my coauthors of the recent ICI chapter entitled "Economics of Urinary and Fecal Incontinence and Prolapse; Report of the 4th International Consultation on Incontinence," L. Subak, T. Wagner, S. DeWachter, and T. Dudding, for their shared intellectual input, some of which will have distilled into the present chapter however unintentionally.

Section III

Structure and Function of the Lower Urinary and Anorectal Tracts in Women

21 Anatomy

John O.L. DeLancey

FUNCTIONAL ANATOMY OF THE LOWER URINARY TRACT

The inseparable relationship between structure and function in living organisms is one of the common themes found in biology. The anatomy and clinical behavior of the lower urinary tract exemplify this immutable link. The following descriptions are intended to offer a brief overview of some clinically relevant aspects of lower urinary tract structure that help us understand the normal and abnormal behavior of this system. Because of the importance of the pelvic floor to lower urinary tract function, comments on the structure of the lower urinary tract organs are followed by a section describing the structure of the pelvic floor as it relates to micturition, continence, and pelvic organ support.

The lower urinary tract can be divided into the bladder and urethra. At the junction of these two continuous, yet discrete, structures lies the vesical neck. This hybrid structure represents that part of the lower urinary tract where the urethral lumen traverses the bladder wall before becoming surrounded by the urethral wall. It contains portions of the bladder muscle and also elements that continue into the urethra.

The vesical neck is considered separately because of its functional differentiation from the bladder and the urethra. The spatial relationships of this region are illustrated in Figure 21.1 and described in Table 21.1.

Bladder

The bladder consists of the detrusor muscle, covered by an adventitia and serosa over its dome and lined by a submucosa and transitional cell epithelium. The muscular layers of the detrusor are not discrete; nevertheless, in general, the outer and inner layers of the detrusor musculature tend to be longitudinal, with an intervening circular–oblique layer.

Two prominent bands on the dorsal aspect of the bladder form one of the prominent landmarks of detrusor musculature [1]. They are derived from the outer longitudinal layer and pass beside the urethra to form a loop on its anterior aspect, called the detrusor loop. On the anterior aspect of this loop, some detrusor fibers leave the region of the vesical neck and attach to the pubic bones and pelvic walls; these are called the pubovesical muscles and are discussed in the succeeding texts.

Trigone

Within the bladder, there is a visible triangular area known as the vesical trigone. The two ureteral orifices and the internal urinary meatus form its apices. The base of the triangle, the interureteric ridge, forms a useful landmark in cystoscopic identification of the ureteral orifices. This triangular elevation is caused by the presence of a specialized group of smooth muscle fibers that lie within the detrusor and arise from a separate embryological primordium. They are continuous above with the ureteral smooth muscle [2]; below, they continue down the urethra. In addition to their visible triangular elevation, these muscle fibers form a ring inside the detrusor loop at the level of the internal urinary meatus [3] (Figure 21.2).

Some fibers continue down the dorsal surface of the urethra and lie between the ends of the U-shaped striated sphincter muscles of the urethra. These smooth muscle fibers of the trigone are clearly separable from those of the detrusor by the smaller size of their fascicles and greater density of surrounding connective tissue. The mucosa over the trigone frequently undergoes squamous metaplasia and therefore differs from that in the rest of the bladder. The circumferential distribution of the trigonal ring fibers at the vesical neck might contribute to closure of the lumen of the vesical neck in this area, but its role has yet to be fully elucidated.

Urethra

The urethra holds urine in the bladder and is therefore an important structure that helps determine urinary continence. Although for many years the urethra was thought to be relatively unimportant in the cause of stress urinary incontinence, recent research has indicated that it is actually the primary factor responsible for stress incontinence. Proper matching of cases with stress incontinence and true asymptomatic controls has revealed that more than 50% of stress incontinence is directly attributable to maximum urethra closure pressure [4].

The urethra is a complex tubular viscus extending below the bladder. In its upper third, it is clearly separable from the adjacent vagina, but its lower portion is fused with the wall of the latter structure. Embedded within its substance are a number of elements that are important to lower urinary tract function; their locations are summarized in Table 21.1 [5]. MRI is being used more frequently to visualize the components of the urethra and suggests functional interpretations of findings in an effort to correlate clinical anatomy with pathophysiology of incontinence [6–8].

Striated Urogenital Sphincter

The outer layer of the urethra is formed by the muscle of the striated urogenital sphincter (Figures 21.3 and 21.4), which is found from approximately 20%–80% of the total urethral length (measured as a percentage of the distance from the internal urinary meatus to the external urinary meatus). In its upper two-thirds, the sphincter fibers lie in a primarily circular orientation; distally, they leave the confines of the urethra and either encircle the vaginal wall as the urethrovaginal sphincter or extend along the inferior pubic ramus above the perineal membrane (urogenital diaphragm) as the compressor urethrae. This muscle is composed largely of slow-twitch muscle fibers [9], which are well suited to maintaining the constant tone exhibited by this muscle. In addition, voluntary muscle activation increases urethral constriction during times when increased closure pressure is needed. In the distal urethra, this striated muscle compresses the urethra from above; proximally, it constricts the lumen. Studies of skeletal muscle blockade suggest that this muscle is responsible for approximately one-third of resting urethral closure pressure [10].

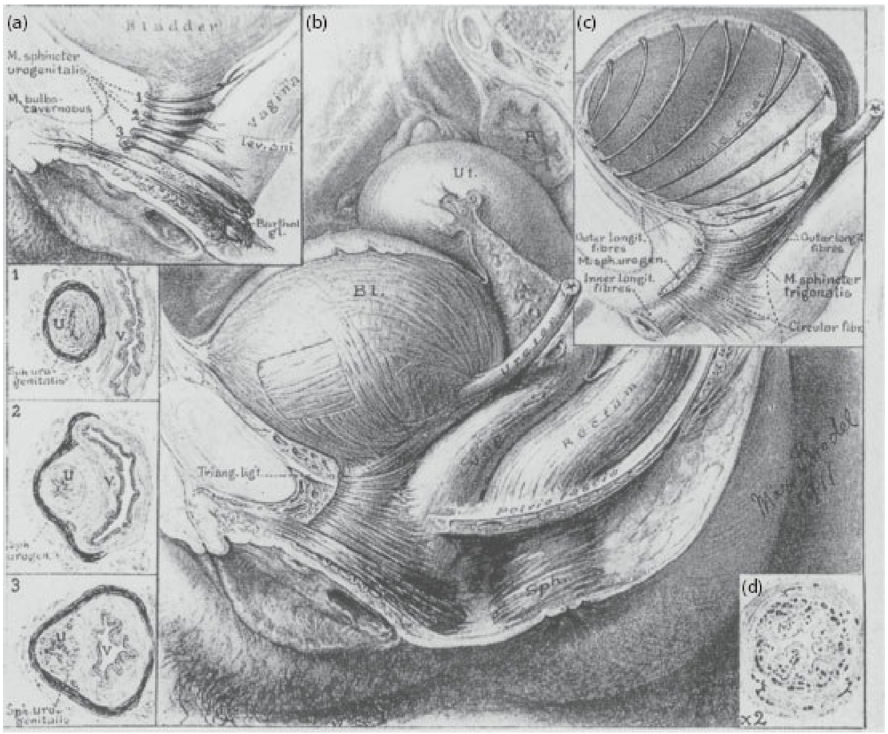

Figure 21.1 The lower urinary tract, including the striated urogenital sphincter muscle. Panel a shows the components of the striated urogenital sphincter muscle with the numbered elements 1, 2, and 3 shown in the following cross section. Panel b represents the relationship of the urethral muscles to the surrounding pelvic organs. Panel c displays the fiber direction of muscles within the detrusor. Panel d indicates the urethra's

vascularity in cross section.

Table 21.1 Topography of Urethral and Paraurethral Structures[a]

Approximate location[b]	Region of the urethra	Paraurethral structures
0–20	Intramural urethra	Urethral lumen traverses the bladder wall
20–60	Midurethra	Sphincter urethrae muscle Pubovesical muscle Vaginolevator attachment
60–80	Perineal membrane	Compressor urethrae muscle Urethrovaginal sphincter muscle
80–100	Distal urethra	Bulbocavernosus muscle

(Reproduced from Oelrich TM, *Anat Rec*, 205, 223, 1983. With permission.)

Recent research has shown that the amount of striated muscle declines considerably with age [11]. This is associated with a decline in innervating nerves [12]. First, vaginal delivery also results in changes in electromyographic patterns of striated sphincter musculature that is consistent with impaired muscular function persisting for at least 6 months beyond delivery [13].

Urethral Smooth Muscle

The smooth muscle of the urethra is contiguous with that of the trigone and detrusor but can be separated from these other muscles on embryological, topographical, and morphological grounds [3,14]. It has an inner longitudinal layer and a thin outer circular layer, with the former being by far the more prominent of the two (Figure 21.5). The layers lie inside the striated urogenital sphincter muscle and are present throughout the upper four-fifths of the urethra. With advancing age, the smooth muscle becomes less dense, a change that may contribute to the decline in urethral closure pressure as women get older [15,16]. The configuration of the circular muscle suggests a role in constricting the lumen, and the longitudinal muscle may help to shorten and funnel the urethra during voiding.

Submucosal Vasculature

Lying within the urethra is a surprisingly well-developed vascular plexus that is more prominent than one would expect for the ordinary demands of so small an organ [17]. These vessels have been studied in serial reconstruction by Huisman [3], who has demonstrated the presence of several specialized types of arteriovenous anastomosis. They are formed in such a way that the flow of blood into large venules can be controlled to inflate or deflate them. This would assist in forming a watertight closure of the mucosal surfaces and offer the possibility of rapid increases in their filling from the pressure on the abdominal vessels that supply them. Occlusion of the arterial inflow to these venous reservoirs has been shown to influence urethral closure pressure [10]. In addition, these appear to be hormonally sensitive [3], which may help to explain some individuals' response to estrogen supplementation.

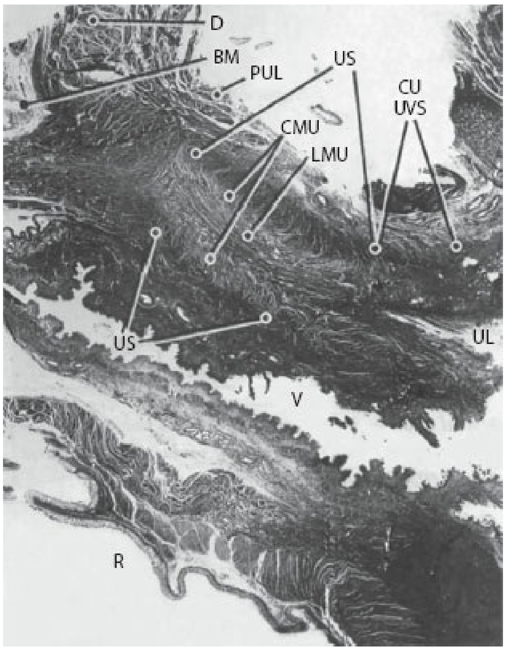

Figure 21.4 Sagittal section from a 29-year-old cadaver, cut just lateral to the midline and not quite parallel to it. The section contains tissue nearer the midline in the distal urethra where the lumen can be seen at the vesical neck. *Abbreviations*: BM, bladder mucosa; CMU, circular smooth muscle of the urethra; CU, compressor urethrae; D, detrusor muscle; LMU, longitudinal smooth muscles of the urethra; PUL, pubourethral ligament; R, rectum; UL, urethral lumen; US, urethral sphincter; UVS, urethrovaginal sphincter; V, vagina. (Reproduced from DeLancey JOL, *Obstet Gynecol*, 68, 91, 1986. With permission.)

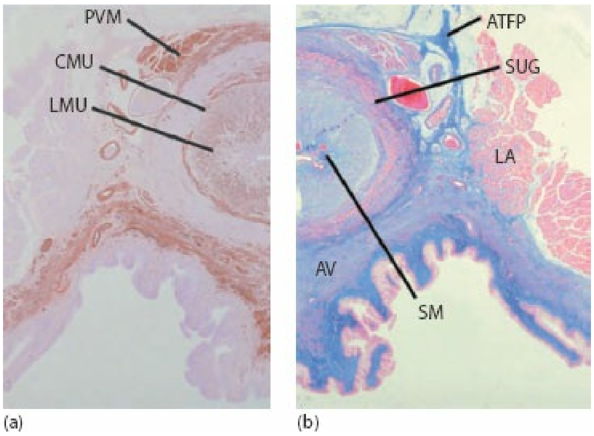

Figure 21.5 Axial midurethral actin immunoperoxidase histological section for smooth muscle (a) and mirrored Mallory trichrome histological section (b) from the same specimen. A few small spots are identified in the submucosa (SM). The longitudinal (LMU) and circular (CMU) smooth muscle of the urethra, the pubovesical muscle (PVM), and the smooth muscle layer of the anterior vaginal wall (AV) are easily identified on the actin-stained immunoperoxidase preparation, whereas the striated urogenital sphincter muscle (SUG) does not stain with actin. *Abbreviations*: ATFP, arcus tendineus fasciae pelvis; LA, levator ani muscles.

Mucosa

The mucosal lining of the urethra is continuous above with the transitional epithelium of the bladder and below with the nonkeratinizing squamous epithelium of the vestibule. This mucosa shares a common derivation from the urogenital sinus with the lower vagina and vestibule. Like these other areas, its mucosa is hormonally sensitive and undergoes significant change, depending on its state of stimulation.

Connective Tissue

In addition to the contractile and vascular tissue of the urethra, there is a considerable quantity of connective tissue interspersed within the muscle and the submucosa. This tissue contains both collagenous and elastin fibers. Studies that have sought to abolish the active aspects of urethral closure have suggested that the noncontractile elements contribute to urethral closure [3]. However, it is difficult to study the function of these tissues because there is no specific way to block their action pharmacologically or surgically.

Glands

A series of glands are found in the submucosa, primarily along the dorsal (vaginal) surface of the urethra [18]. They are most concentrated in the lower and middle thirds and vary in number. The location of urethral diverticula (which are derived from cystic dilation of these glands) follows this distribution, being the most common distally and usually originating along the dorsal surface of the urethra. In addition, their origin within the submucosa indicates that the fascia of the urethra must be stretched and attenuated over their surface and indicates the need for its approximation after diverticular excision.

Vesical Neck

The term “vesical neck” is both a regional and a functional one, as previously discussed. It does not refer to a single anatomic entity; it denotes that area, at the base of the bladder, where the urethral lumen passes through the thickened musculature of the bladder base. Therefore, it is sometimes considered as part of the bladder musculature, but it also contains the urethral lumen studied during urethral pressure profilometry. It is a region where the detrusor musculature, including the detrusor loop, surrounds the trigonal ring and the internal urinary meatus.

The vesical neck has come to be considered separately from the bladder and urethra because it has unique functional characteristics. Specifically, sympathetic denervation or damage of this area results in its remaining open at rest [19]; when this happens in association with stress incontinence, simple urethral suspension is often ineffective in curing this problem [20].

Functional Terms

A number of terms have been used to describe functional units within the vesicourethral unit, based upon radiographic observations of the activities of these viscera. The term “extrinsic continence mechanism” or “external sphincteric mechanism” usually refers to that group of structures that respond when an individual is instructed to stop the urine stream. The two phenomena observed during this effort are a constriction of the urethral lumen by the striated urogenital sphincter and an elevation of the vesical neck, caused by contraction of the levator ani muscles, as described in the following texts. The intrinsic continence mechanism then consists of the structures that lie within the vesical neck and are not specifically activated by contraction of the voluntary muscles. It is this system that fails in patients whose vesical neck can be seen to be open at rest.

PELVIC FLOOR

The position and mobility of the bladder and urethra are recognized as important to urinary continence [21]. Although urethral support plays a secondary role in causing stress incontinence, it is still an independent and important factor [4]. Because these two organs are limp and formless when removed from the body, they must depend upon attachments to the pelvic floor for their shape and position. Fluoroscopic examination has shown that the upper portions of the urethra and vesical neck are normally mobile structures, whereas the distal urethra remains fixed in position [22,23]. The pelvic floor muscles and fasciae determine these aspects of support and fixation. The term “pelvic floor” is used in different ways by different authors. Sometimes, especially in the colorectal field, the term is used to refer to the levator ani muscles. In this chapter, it will be given its broader interpretation because the anatomic term “pelvic diaphragm” serves to identify levator ani muscles and their covering fascia, leaving the term “pelvic floor” to identify the complex structural unit that lies at the bottom of the abdominal cavity.

The pelvic floor consists of several components lying between the pelvic peritoneum and the vulvar skin. These are (from above downward) the peritoneum, viscera and endopelvic fascia, levator ani muscles, perineal membrane, and external genital muscles. The eventual support for all of these structures comes from their connection to the bony pelvis and its attached muscles. The viscera are often thought of as being supported by the pelvic floor; however, they are actually a part of it. Through such structures as the cardinal (CL) and uterosacral ligaments (USLs) and the pubocervical fascia, the viscera have an important role in forming the pelvic floor.

Endopelvic Fascia

Viscerofascial Layer

The top layer of the pelvic floor is provided by the endopelvic fascia that attaches the pelvic organs to the pelvic walls, thereby suspending the pelvic organs [24–26]. Because this layer is a combination of the pelvic viscera and the endopelvic fascia, it is referred to here as the viscerofascial layer. It is common to speak of the fasciae and ligaments alone, separate from the pelvic organs as if they had a discrete identity; however, unless these fibrous structures have something to attach to (the pelvic organs), they can have no mechanical effect.

On each side of the pelvis, the endopelvic fascia attaches the uterus and vagina to the pelvic wall (Figures 21.6 through 21.8). This fascia forms a continuous sheetlike mesentery, extending from the uterine artery at its cephalic margin to the point at which the vagina fuses with the levator ani muscles below. The part that attaches to the uterus is called the parametrium and that which attaches to the vagina, the paracolpium.

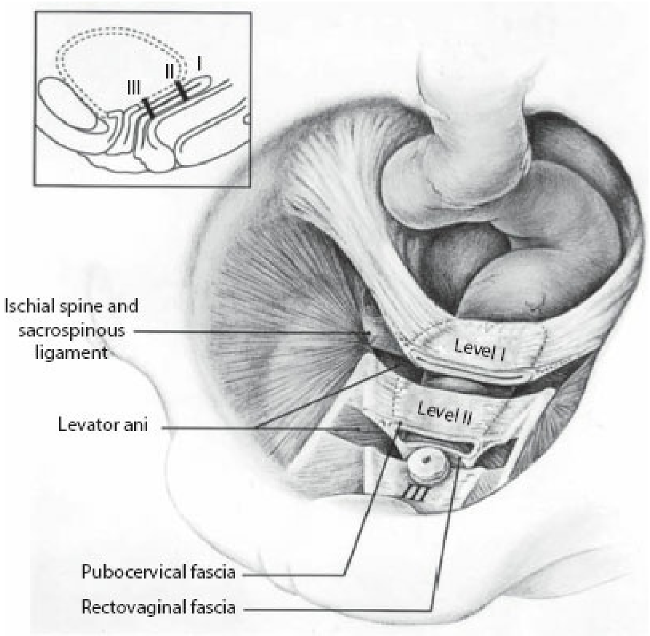

Figure 21.8 Level I (suspension) and level II (attachment). In level I, the paracolpium suspends the vagina from the lateral pelvic walls. Fibers of level I extend both vertically and posteriorly toward the sacrum. In level II, the vagina is attached to the arcus tendineus fasciae pelvis and superior fascia of levator ani. (Reproduced from DeLancey JOL, *Am J Obstet Gynecol*, 166, 1717, 1992. With permission.)

The parametria are made up of what are clinically referred to as the CL and USL [27,28].

Although the cardinal and uterosacrals are termed “ligaments” and “fasciae,” they are not the same type of tissue as that seen in the “fascia” of the rectus abdominis muscle or in the ligaments of the knee, both of which are composed of parallel collagen fibers forming dense, regular, connective tissue. The CL consists of blood vessels, nerves, and fibrous connective tissue and can be thought of as mesenteries that supply the genital tract bilaterally. The USL contains a specific body of smooth muscle not contained in the CL that attaches to the dorsal surface of the cervix. The ridge formed by these tissues when the uterus is elevated is visible when the cul de sac is viewed from above and is the most familiar view of this structure but looks entirely different when the uterus is drawn downward, the action that demonstrates its supportive function.

The structural effect of the CL and USL is most evident when the uterine cervix is pulled downward with a tenaculum, as occurs during dilation and curettage. After a certain amount of descent within the elastic range of the fascia, the parametria become tight and arrest the further cervical descent. Similarly, downward descent of the vaginal apex after hysterectomy is resisted by the paracolpium. The fact that these ligaments do not determine the position of the uterus in normal healthy women is attested to by the observation that the cervix may be pulled down to the level of the hymen with little difficulty [29], and significant differences exist between the location of the cervix during Valsalva in the clinic and with traction in the operating room. In women with normal support, there is a difference of 5 cm or more in most instances [30].

Although it is traditional to focus attention on the ligaments that suspend the uterus, the attachments of the vagina to the pelvic walls are equally important and are responsible for normal support of the vagina, bladder, and rectum, even after hysterectomy. The location of damage to these supports determines whether a woman has a cystocele, rectocele, or vaginal vault prolapse; understanding the different characteristics of this support helps in the understanding of the different types of prolapse that can occur.

After hysterectomy, the upper two-thirds of the vagina is suspended and attached to the pelvic walls by the paracolpium [26]. This paracolpium has two portions (see Figure 21.8): the upper portion (level I) consists of a relatively long sheet of tissue that suspends the vagina by attaching it to the pelvic wall; in the midportion of the vagina, the paracolpium attaches the vagina laterally and more directly to the pelvic walls (level II). This attachment stretches the vagina transversely between the bladder and rectum and has functional significance. The structural layer that supports the bladder (“pubocervical fascia”) is composed of the anterior vaginal wall and its attachment through the endopelvic fascia to the pelvic wall. It is not a layer separate from the vagina, as sometimes suggested, but is a combination of the anterior vaginal wall and its attachments to the pelvic wall. Similarly, the posterior vaginal wall and endopelvic fascia (rectovaginal fascia) form the restraining layer that prevents the rectum from protruding forward, blocking the formation of a rectocele. In the distal vagina (level III), the vaginal wall is directly attached to surrounding structures without any intervening paracolpium: anteriorly it fuses with the urethra, posteriorly with the perineal body, and laterally with the levator ani muscles.

Loss of level II support occurs because of detachment of the arcus tendineus from the ischial spine rather than from the pubic bone [31]. This allows the trapezoidal-shaped anterior vaginal wall to swing downward, resulting in the characteristic cystocele seen clinically. There is also some failure of the midline vaginal wall in these patients, and the relationship between these two defects remains to be clarified.

With the advent of high-resolution MRI, it has been possible to examine the distinct anatomy of the CL and the deep uterosacral ligament (USLd) that comprise the parametrium. Although the superficial USLs that are seen during abdominal hysterectomy are not visible on MRI, the USLds are; their anatomy can, therefore, be studied [32]. The orientation of the CL and USLd and also the changes that occur during increases in abdominal pressure can be studied using models based on women with and without pelvic organ prolapse (Figure 21.9) [33]. In normal women, the CLs are 18.1° ± 6.8° (SD) from the vertical body axis (head to foot) going from their origin at the top of the greater sciatic foramen to their insertion on the cervix and upper vagina. The USLds are dorsally directed at 92.5° ± 13.5 from the body axis coursing from their origin near the sacral foramina S2–S4. The CLs are longer and more curved than USL. When simulated loads are applied in biomechanical models, the theoretical calculated tension on CL is 52% larger than that on USL [34]. These ligament tensions are affected by their orientations.

The differences between these ligaments in women with (cases) and without (controls) prolapse have also been studied. The curved length of the CL at rest was 71 ± 16 mm (cases) vs. 59 ± 9 mm (controls; $p = 0.05$). For the deep uterosacral values, these values were 38 ± 16 mm vs. 36 ± 11 mm ($p = 0.8$), respectively. Similarly, the increase in CL length from rest to strain was 30 ± 16 mm vs. 15 ± 9 mm ($p = 0.03$), and USLd was 15 ± 12 mm vs. 7 ± 4 mm ($p = 0.09$). The change in deep uterosacral angle from rest to Valsalva was significantly different from the CL ($p < 0.001$). These data reveal that CL elongation was greater in women with prolapse than in women with normal support, whereas USL length change was not. The USLd exhibited greater changes in ligament inclination angle [35] (see

Figure 21.10).

The mechanical properties of these ligaments have been studied in vivo by applying known amounts of traction force on the cervix while measuring cervical displacement. In these studies, the length of the CL (indicated by the location of the cervix) seems to be the primary factor associated with cervix position during clinical examination with ligament stiffness playing a relatively minor role [36]. Changes in apical support have clinical importance to both uterine prolapse and cystocele because slightly more than half of cystocele size is associated with the degree to which the cervix prolapses [37].

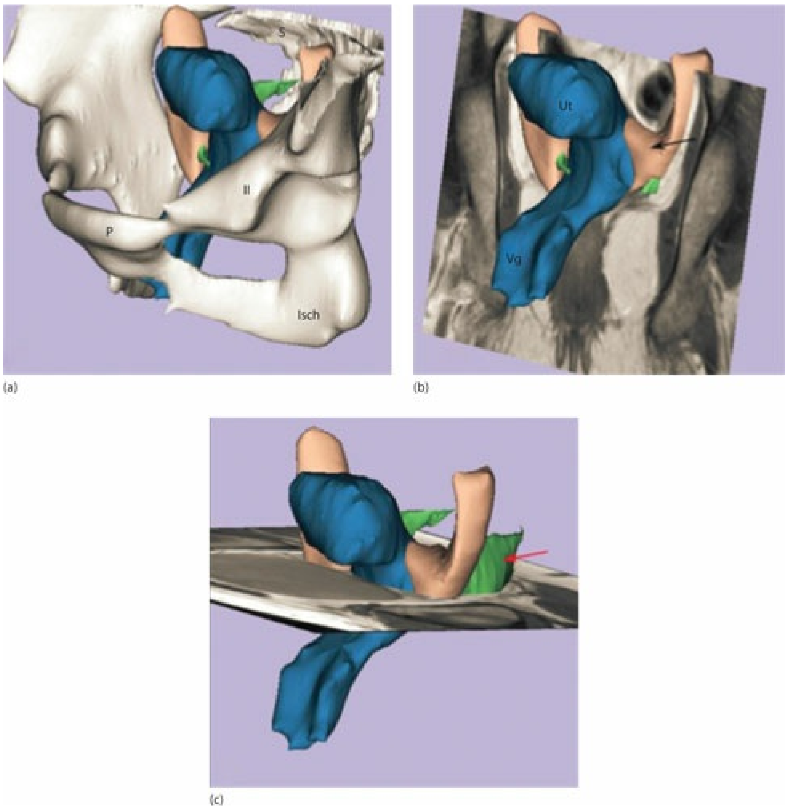

Figure 21.9 A 3D model of the cardinal ligament and uterosacral ligament is oriented relative to the coronal and axial planes. (a) The bony pelvis, including the pubis (P), ilium (Il), ischium (Isch), and sacrum (S), is displayed. (b) Positioning of the uterus (Ut), cardinal ligament (black arrow), and vagina (Vg) can be seen in this coronal image. (c) Note the location of the uterosacral ligament (red arrow) in this axial MR scan. (Courtesy of DeLancey.)

Pelvic Diaphragm and Levator Ani Muscles

Subjecting connective tissue to constant force will stretch any such tissue within the body. Skin expanders used in plastic surgery stretch the dense and resistant dermis to extraordinary degrees, and flexibility exercises practiced by dancers and athletes elongate leg ligaments with as little as 10 minutes of stretching a day. Both of these observations underscore the malleable nature of connective tissue when subjected to force overtime. If the ligaments and fasciae within the pelvis were subjected to the continuous stress imposed on the pelvic floor by the great weight of abdominal pressure, they would stretch; this stretching does not occur because the pelvic floor muscles close the pelvic floor and carry the weight of the abdominal and pelvic organs, preventing constant strain on the ligaments. Recent research has demonstrated the importance of levator ani muscle defects in the occurrence of pelvic organ prolapse [38]. Fifty-five percent of women with prolapse have major injuries to their levator ani muscles. Only 16% of the normal population have this level of injury. Therefore, women with prolapse are much more likely to have major levator muscle injury. This injury is associated with loss of levator contraction force and a larger urogenital hiatus. There is also evidence that poorly functioning levator ani muscles are associated with surgical failure [39].

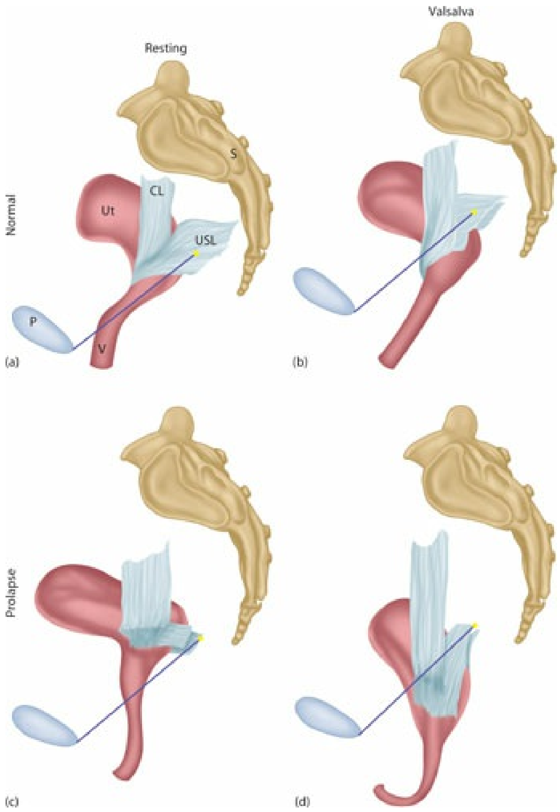

Figure 21.10 Normal and prolapse ligament comparison under resting and maximal Valsalva. Left side view of 3D models of one healthy individual at rest (a) and at maximal Valsalva (b), with their relationship to the normalized arcus tendineus fasciae pelvis (ATFP) (turquoise lines extending from the pubic symphysis [PS] to the ischial spines [yellow squares] or the pubic symphysis to the ischial spine line for spatial reference). Left side view of models of one individual with prolapse at rest (c) and at maximal Valsalva (d). PS and sacrum are shown in the midsagittal plane. *Abbreviations*: Ut, uterus; V, vagina; CL, cardinal ligament; USLd, deep uterosacral ligament. (Courtesy of DeLancey.)

Below the viscerofascial layer is the levator ani group of muscles [40] (Figure 21.11). They have a connective tissue covering on both superior and inferior surfaces, known as the superior and inferior fasciae of the levator ani, respectively. When these muscles and their fasciae are considered together, the combined structure is termed the “pelvic diaphragm.” Although there have been disagreements about the terminology for this muscle, recent review of the literature shows good unanimity regarding anatomy, and a consistent nomenclature based on standardized anatomic terminology is possible [41].

There are three portions of the levator ani muscle: the pubovisceral (pubococcygeal), puborectal, and iliococcygeal [42,43]. The pubovisceral and puborectal muscles arise from the pubic bones on either side of the midline. The pubovisceral muscle lies medial to the puborectal muscle and has several identifiable portions, each with a specific insertion point: The puboperineal portion attaches to the perineal body, the pubovaginal portion attaches to the lateral vaginal wall just inside the hymen, and the puboanal portion has fibers insert into the space between the internal and external anal sphincter. The puborectal muscle originates near the pubic bone and from the superior surface of the perineal membrane and forms a sling dorsal to the anorectal angle, just cranial to the external anal sphincter. Laterally, the iliococcygeal muscle arises from a fibrous band on the pelvic wall (arcus tendineus levator ani [ATLA]) and forms a relatively horizontal sheet that spans the opening within the pelvis and provides a shelf on which the organs may rest. The muscle inserts into the iliococcygeal raphe that is connected to the inner surface of the coccyx and sacrum.

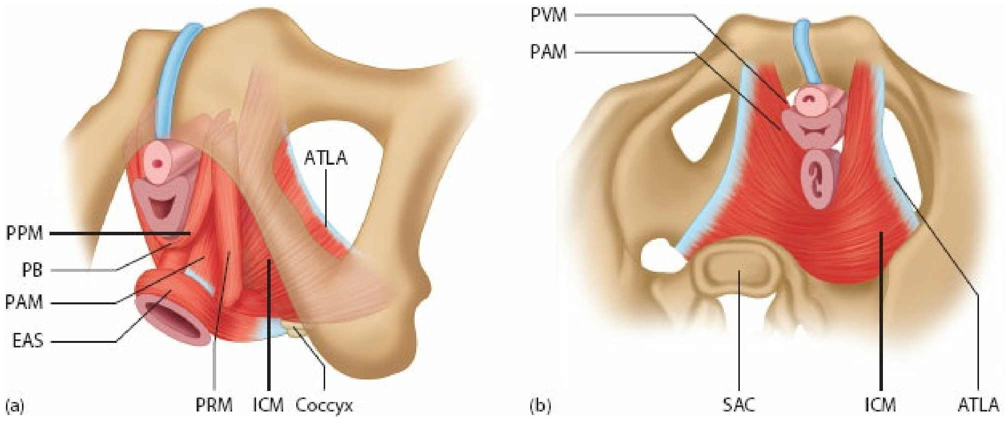

Figure 21.11 (a) The levator ani muscles from below after the vulvar structures and perineal membrane have been removed showing the arcus tendineus levator ani (ATLA), external anal sphincter (EAS), puboanal muscle (PAM), perineal body (PB) uniting the two ends of the puboperineal muscle (PPM), iliococcygeal muscle (ICM), and puborectal muscle (PRM). The urethra and vagina have been transected just above the hymenal ring. (b) The levator ani muscle seen from above looking over the sacral promontory (SAC) showing the pubovaginal muscle (PVM; other abbreviations as in Figure 21.11a). The urethra, vagina, and rectum have been transected just above the pelvic floor. *Note*: The internal obturator muscles have been removed to clarify levator muscle origins. (Reproduced from Kearney R et al., *Obstet Gynecol*, 104, 168, 2004. With permission.)

The opening within the levator ani muscle through which the urethra and vagina pass (and through which prolapse occurs) is called the urogenital hiatus of the levator ani. The rectum also passes through this opening; however, because the levator ani muscles attach directly to the anus, it is not included in the name of the hiatus. The hiatus, therefore, is bounded ventrally (anteriorly) by the pubic bones, laterally by the levator ani muscles, and dorsally (posteriorly) by the perineal body and external anal sphincter. The normal baseline activity of the levator ani muscle keeps the urogenital hiatus closed: it squeezes the vagina, urethra, and rectum closed by compressing them against the pubic bone and it lifts the floor and organs in a cephalic direction.

The levator ani muscles have constant activity [44], like that of other postural muscles. This continuous contraction is similar to the continuous activity of the external anal sphincter muscle and closes the lumen of the vagina in a way similar to that by which the anal sphincter closes the anus. This constant action eliminates any opening within the pelvic floor through which prolapse could occur and forms a relatively horizontal shelf on which the pelvic organs are supported [45,46]. The mechanical action of a muscle is determined by the direction of its fibers. Within the levator ani muscles, there is a 60° differences in muscle fiber direction between the puborectal and pubovisceral muscles [47] (Figure 21.12).

The mechanical consequences of this difference can be appreciated by resolving the muscle fiber directions into a horizontal component that would lead to closure of the levator hiatus and a vertical component that would result in elevation (Figure 21.13). Both the pubovisceral and puborectal components have a significant horizontal component that would compress the hiatus closed. By contrast, only the pubovisceral muscle has an upward vertical vector that could play a role in elevation. The vertical vector of the puborectal muscle is actually in a slight downward direction. The fact that birth-associated injury to the levator ani muscle only affects the pubococcygeal muscle [48] means that distinguishing between these muscles is important in understanding the consequences of levator injury.

Interaction between the Muscle and Connective Tissue

It is important to recognize that the degree of ligament impairment and the degree of prolapse are influenced by and interact with the status of the levator ani muscles as well [49–51]. Figure 21.14 explains this interaction [52]. With normal levator function, (a) the vaginal walls are in apposition, and anterior and posterior pressures are balanced. Levator damage (b) results in hiatal opening. In this situation, the vagina becomes exposed to a pressure differential between abdominal and atmospheric pressures. This pressure differential (c) creates a traction force on the CL and USL.

The importance of understanding the relationship of musculature support and connective tissue support [50,51].

As long as the levator ani muscles function properly, the pelvic floor is closed and the ligaments and fascia are under no tension; the fasciae simply act to stabilize the organs in their position above the levator ani muscles. When the pelvic floor muscles relax or are damaged, the pelvic floor opens and the vagina lies between the high abdominal pressure and low atmospheric pressure; in this situation, it must be held in place by the ligaments. Although the ligaments can sustain these loads for short periods of time, if the pelvic floor muscles do not close the pelvic floor, then the connective tissue must carry this load for long periods and will eventually fail to hold the vagina in place. Song and colleagues have recently shown that there is a decrease in collagen type III in premenopausal women with stress incontinence, suggesting that less flexibility of connective tissue may be associated with greater likelihood of eventual loss of vaginal support [53].

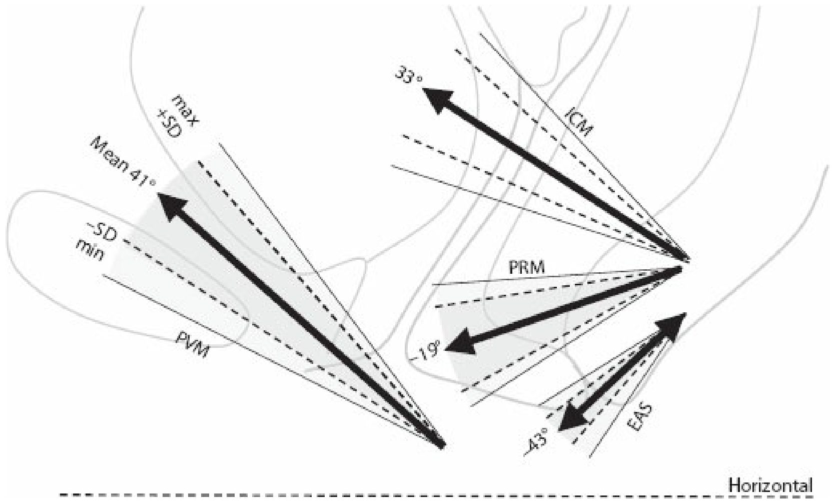

Figure 21.12 The thick arrow displays the mean direction to the horizontal line in a 2D graphic while the shaded areas reflect the standard deviations and range. The dashed line is the horizontal line from which the angles are measured. Angles above the horizontal line have a "±" sign and those below the horizontal line a "−" sign. (Courtesy of DeLancey.)

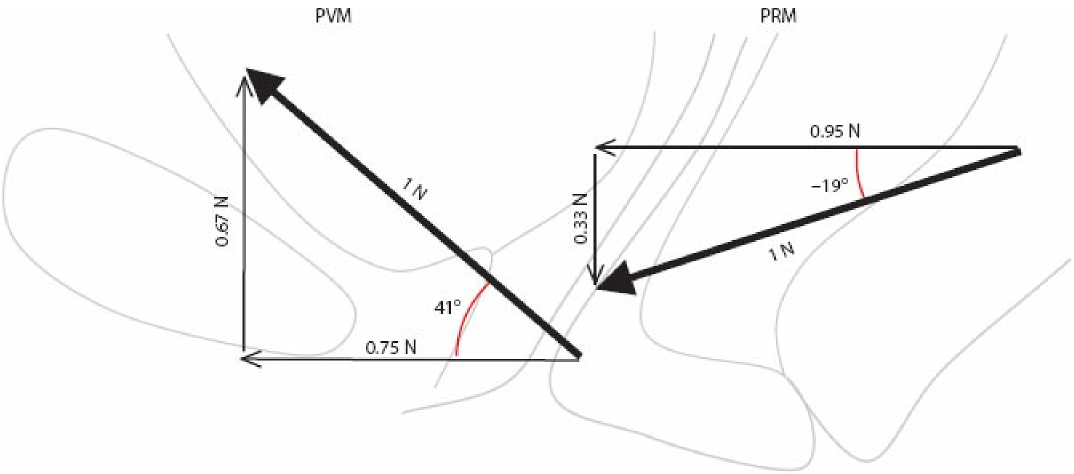

Figure 21.13 Horizontal and vertical components of the pubovaginal muscle (PVM) and puborectal muscle (PRM) in the standing position. The thick arrows show the average direction of the lines of action of the PVM and PRM relative to the horizontal with a theoretical 1 N force. Thin lines indicate the portion of each force related to a closing and lifting function. (*Note*: Vectors are shown larger than the background anatomy to avoid an overlap in the display.) (Courtesy of DeLancey.)

This support of the uterus has been likened to a ship in its berth, floating on the water attached by ropes on either side to a dock [54]. The ship is analogous to the uterus, the ropes to the ligaments, and the water to the supportive layer formed by the pelvic floor muscles. The ropes (ligaments) function to hold the ship (uterus) in the center of its berth as it rests on the water (pelvic floor muscles). If, however, the water level were to fall so far that the ropes would be required to hold the ship without the support of the water, the ropes would break. The analogous situation in the pelvic floor involves the pelvic floor muscles supporting the uterus and vagina that are stabilized in position by the ligaments and fasciae: once the pelvic floor musculature becomes damaged and no longer holds the organs in place, the connective tissue fails because of significant overload.

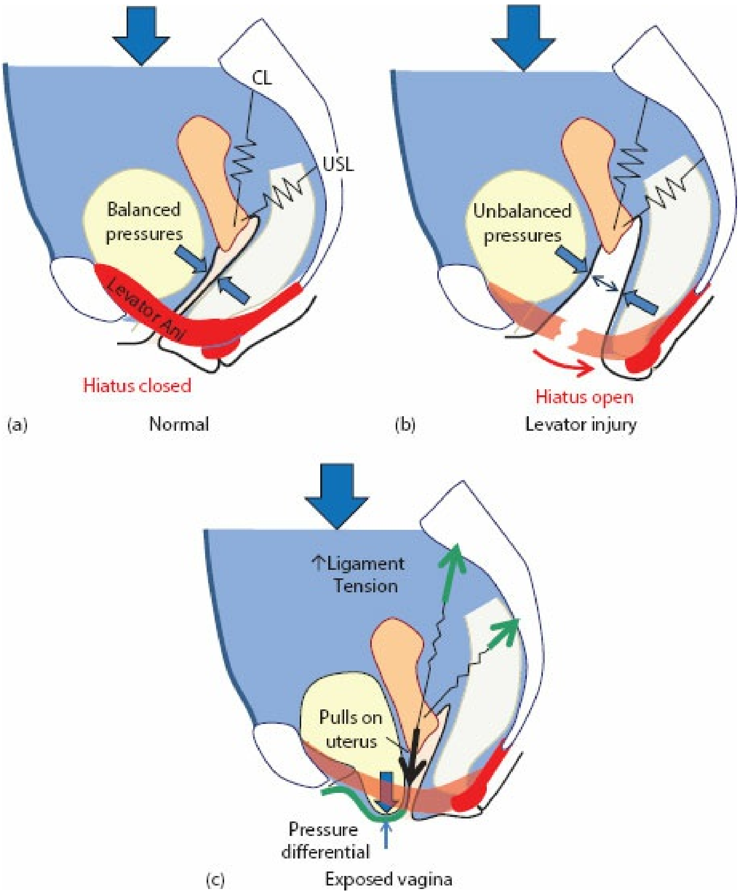

Figure 21.14 Diagrammatic representation of interactions between levator ani muscle, anterior vaginal wall prolapse, and cardinal/uterosacral ligament suspension. (a) Normal levator, pressures balanced; (b) damaged levator, hiatus opens; and (c) pressure differential, upward ligament tension. (Courtesy of DeLancey.)

Perineal Membrane and External Genital Muscles

In the anterior portion of the pelvis, below the pelvic diaphragm, is a dense triangular membrane containing a central opening called the perineal membrane (urogenital diaphragm). This lies at the level of the hymenal ring and attaches the urethra, vagina, and perineal body to the ischiopubic rami. Just above the perineal membrane are the compressor urethrae and urethrovaginal sphincter muscles, previously discussed as part of the striated urogenital sphincter muscle.

Recent dissections show the intimate relationship between the perineal membrane and the levator ani muscle (Figure 21.15); these are in close proximity and so the action of the muscle certainly could influence the position of the perineal membrane [55].

The term "perineal membrane" replaces the old term "urogenital diaphragm," reflecting more accurate recent anatomic information [56]. Previous concepts of the urogenital diaphragm show two fascial layers, with a transversely orientated muscle between them (the deep transverse perineal muscle). Observations based on serial histology and gross dissection, however, reveal a single connective tissue membrane, with these muscles and the levator ani muscles lying immediately above.

The correct anatomy explains the observation that pressures during a cough are greatest in the distal urethra [57,58], where the compressor urethrae and urethrovaginal sphincter can squeeze the lumen in anticipation of a cough [59]. The perineal membrane has been visualized in normal women by MRI examination [8].

Position and Mobility of the Urethra

When the importance of urethral position to determining urinary continence was recognized, anatomic observations revealed an attachment of the tissues around the urethra to the pubic bones. These connections were referred to as the pubourethral ligaments [60] and were found to be continuous with the connective tissue of the perineal membrane [61]. Further studies [59,62,63] have expanded these observations and revealed several separate structural elements contained within these—tissues that have functional importance to urinary—continences [64].

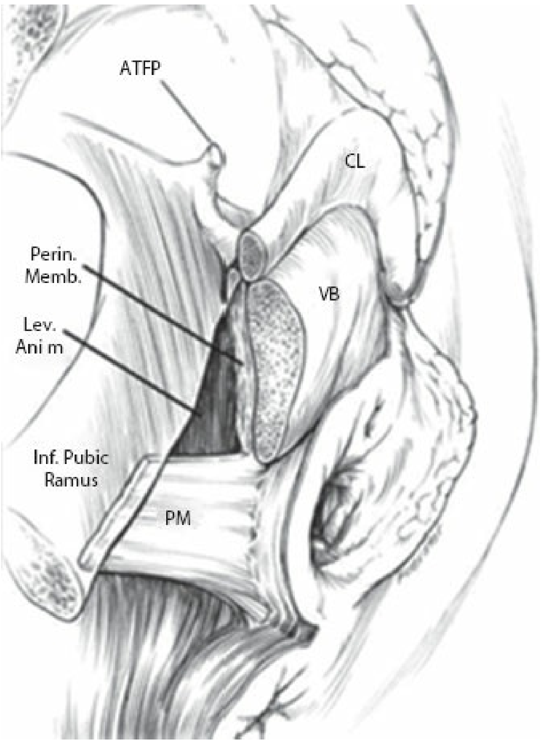

Figure 21.15 Drawing of dissection revealing the perineal membrane showing its lateral attachment to the inferior pubic ramus. A window in the perineal membrane has been cut to reveal the attachment of the levator ani muscle and its fusion with the vestibular bulb. Extension to the arcus tendineus fasciae pelvis is also shown, which is seen inside the pubic bone attaching to its inner surface, clitoris. (From Stein TA and DeLancey JO, *Obstet Gynecol*, 111, 686, 2008. Copyright DeLancey.)

As mentioned earlier in this chapter, urethral support is dynamic rather than static. Fluoroscopic and topographic observations [22,23] suggest that urethral position is determined both by attachments to the bone and by those to the levator ani muscles. The role of the connection between the ureteral supports and those to the levator ani is probably more important than previously thought for the following reasons:

- The resting position of the proximal urethra is high within the pelvis, some 3 cm above the inferior aspect of the pubic bones [65] (Figure 21.16) and above the insertion of the “posterior pubourethral ligaments,” which attach near the lower margin of the pubic bones [60].
- Maintenance of this position would be best explained by the constant muscular activity of the levator ani. In addition, the upper two-thirds of the urethra is mobile [22,23,66] and under voluntary control.
- At the onset of micturition, relaxation of the levator ani muscles allows the urethra to descend

and obliterates the posterior urethrovesical angle (Figure 21.16).

- Resumption of the normal tonic contraction of the muscle at the end of micturition returns the vesical neck to its normal position.

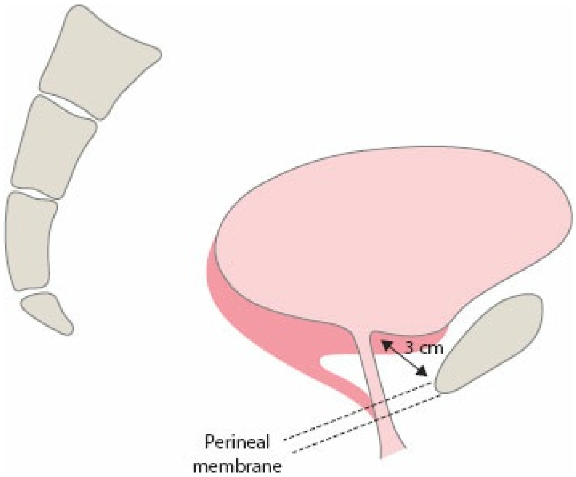

Figure 21.16 Topography and mobility of the normal proximal urethra and vesical neck based upon resting (▪) and voiding (▪) in nulliparae.

Both urethral function and urethral support play a role in urinary continence. Although previously it was thought that support was the predominant factor, it is now clear that urethral function (maximal urethral closure pressure) is the primary determinant of whether or not a woman has stress incontinence [4]. Urethral support is probably more influential in younger women with stress urinary incontinence because they have relatively good urethral function. As urethral function declines with age, the role that maximum urethral closure pressure plays begins to predominate. In women with de novo stress incontinence after first birth, injury to the levator ani muscle is seen twice as often as individuals who deliver and are continent [67]. Later on in life, this seems, however, to disappear [4].

The anterior vaginal wall and urethra arise from the urogenital sinus and are intimately connected. The support of the urethra does not depend on attachments of the urethra itself to adjacent structures, but on the connection of the vagina and periurethral tissues to the muscles and fasciae of the pelvic wall. Surgeons are most familiar with seeing this anatomy through the space of Retzius, and this view is also helpful in understanding urethral support (Figure 21.17). On either side of the pelvis, the arcus tendineus fasciae pelvis (ATFP) is found as a band of connective tissue attached at one end to the lower one-sixth of the pubic bone, 1 cm from the midline, and at the other end to the ischial spine. The anterior portion of this band lies on the inner surface of the levator ani muscle that arises some 3 cm above the ATFP. Posteriorly, the levator ani arises from a second arcus, the ATLA, which fuses with the ATFP near the ischial spine.

The layer of tissue that provides urethral support has two lateral attachments: a fascial attachment and a muscular attachment (Figure 21.18). The fascial attachments of the urethral supports connect the periurethral tissues and anterior vaginal wall to the ATFP and have been termed the “paravaginal fascial attachments” [62]. The muscular attachment connects these same periurethral tissues to the medial border of the levator ani muscle. These attachments allow the normal resting tone of the levator ani to maintain the position of the vesical neck, supported by the fascial attachments (Figure 21.19). When the muscle relaxes at the onset of micturition, it allows the vesical neck to rotate downward to the limit of the elasticity of the fascial attachments; at the end of micturition, contraction allows it to resume its normal position.

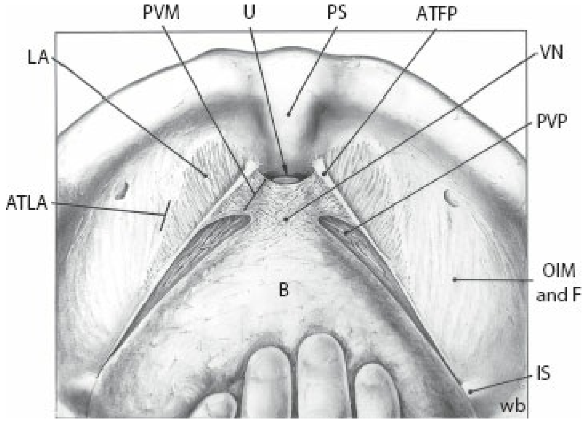

Figure 21.17 Space of Retzius (drawn from cadaver dissection). Pubovesical muscle can be seen going from vesical neck to arcus tendineus fasciae pelvis and running over the paraurethral vascular plexus. *Abbreviations*: ATLA, arcus tendineus levator ani; B, bladder; IS, ischial spine; LA, levator ani muscles; OIM and F obturator internus muscle and fascia; PS, pubic symphysis; U, urethra. (Reproduced from DeLancey JOL, *Neurourol Urodyn*, 8, 53, 1989. With permission.)

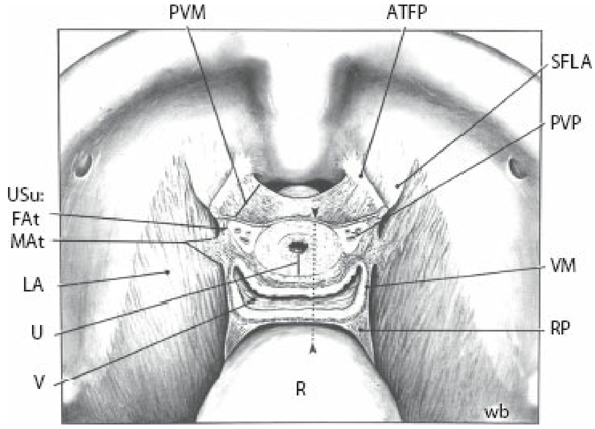

Figure 21.18 Relationship of the supportive tissues of the urethra (USu) to the pubovesical muscles (PVM). Cross section of the urethra (U), vagina (V), arcus tendineus fasciae pelvis (ATFP), and superior fascia of levator ani (SFLA) just below the vesical neck (drawn from cadaver dissection). The PVM lie anterior to the urethra, and anterior and superior to the paraurethral vascular plexus. The USu ("the pubourethral ligaments") attach the vagina and vaginal surface of the urethra to the levator ani (LA) muscles (muscular attachment) and to the SFLA (fascial attachment). *Abbreviations*: R, rectum; RP, rectal pillar; VM, vaginal wall muscularis. (Reproduced from DeLancey JOL, *Neurourol Urodyn*, 8, 53, 1989. With permission.)

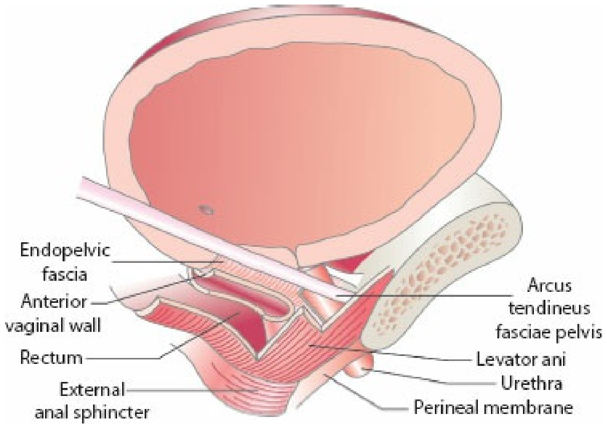

Figure 21.19 Lateral view of the pelvic floor structures related to urethral support, seen from the side in the

standing position cut just lateral to the midline. Note that windows have been cut in the levator ani muscles, vagina, and endopelvic fascia so that the urethra and anterior vaginal walls can be seen.

Also within this region are the pubovesical muscles, which are extensions of the detrusor muscle [1,68,69]. They lie within the connective tissue; when both muscular and fibrous elements are considered together, they are termed the "pubovesical ligaments," in much the same way that the smooth muscle of the ligamentum teres is referred to as the round ligament (see Figures 21.4, 21.5, 21.17, and 21.18). Although the terms "pubovesical ligament" and "pubourethral ligament" have sometimes been considered to be synonymous, the pubovesical ligaments are different structures from the urethral supportive tissues. Fibers of the detrusor muscle are able to undergo great elongation, and these weak tissues are, therefore, not suited to maintain urethral position under stress. In addition, they run in front of the vesical neck rather than underneath it, where one would expect supportive tissues to be found. It is not surprising, therefore, that these detrusor fibers do not differ, in stress-incontinent patients, from those in patients without this condition [70]. The tissues that support the urethra are separated from the pubovesical ligaments by a prominent vascular plexus and are easily parted from them. Rather than supporting the urethra, the pubovesical muscles may be responsible for assisting in vesical neck opening at the onset of micturition by contracting to pull the anterior vesical neck forward, as some have suggested [71].

This mechanism influences incontinence by determining how the urethra is supported, not by how high or low the urethra is in the pelvis. In examining anatomic specimens, simulated increases in abdominal pressure reveal that the urethra lies in a position where it can be compressed against the supporting hammock by rises in abdominal pressure (Figure 21.19). In this model, it is the stability of this supporting layer under the urethra rather than the height of the urethra that determines stress continence. In an individual with a firm supportive layer, the urethra would be compressed between abdominal pressure and pelvic fascia (Figure 21.20) in much the same way that the flow of water through a garden hose can be stopped by stepping on and compressing it against underlying paving. If, however, the layer under the urethra becomes unstable and does not provide a firm backstop against which the urethra can be compressed by abdominal pressure, the opposing force that causes closure is lost and the occlusive action is diminished. This latter situation is similar to an attempt to stop the flow of water through a garden hose by stepping on it while it lies on soft soil.

The structural and functional aspects of the body must always be in agreement. As new functional observations are made of the lower urinary tract, it will be necessary to reexamine our anatomic concepts; doubtless, some of the structural arrangements described in this chapter will be corrected, expanded upon, and improved. This will continue to enhance our ability to understand the variety of patients with lower urinary tract dysfunction and will improve our ability to restore normal urinary control.

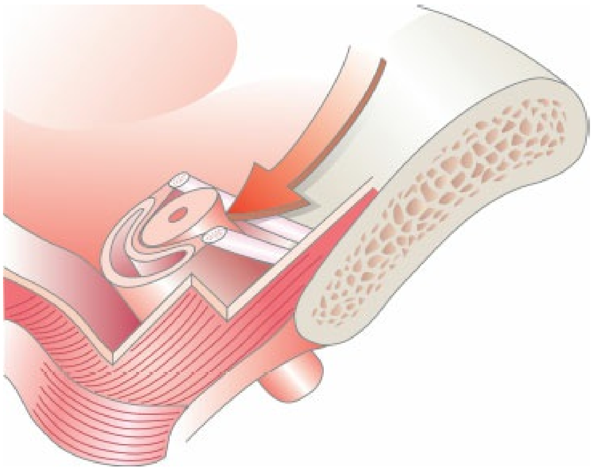

Figure 21.20 Lateral view of pelvic floor with the urethra, vagina, and fascial tissues transected at the level of the vesical neck, drawn from 3D reconstruction indicating compression of the urethra by downward force (arrow) against the supportive tissues indicating the influence of abdominal pressure on the urethra (arrow).

Embryology of the Female Urogenital System and Clinical Applications

Dana Weiss and Stephen A. Zderic

INTRODUCTION

The first goal of this chapter is to provide an overview of the embryological events that lead to the formation of the upper and lower urinary tract in women. Normal female lower urinary tract development cannot be discussed in isolation from that of the rectum, anus, and vagina. Therefore, a good deal of attention will be focused on the embryology of the cloaca and the process whereby it is transformed into the perineum. The traditional embryology literature was highly descriptive based on clinical observations and two-dimensional line drawings. The modern world of developmental biology has changed as embryology may now be visualized in three dimensions, and congenital defects can be examined during the course of development using mice with targeted genetic anomalies. The second goal of this chapter is to briefly discuss the genetic and molecular signals that enable these complex structures to develop. The final goal of this chapter is to provide clinical examples of malformations that arise when deviations from this path of normal development occur.

A growing database of murine genitourinary development exists within the GenitoUrinary Development Molecular Anatomy Project (gudmap.org), which includes serial sections of murine embryos at various stages of development. Over the past 10 years, this multicenter collaboration has compiled a large database containing the results of in situ hybridizations and immunohistochemistry performed for specific gene and protein expression, as well as microarray data. These results are available as a common resource for all investigators via the online portal and serve as a rich starting point from which new work can be planned or current findings can be compared with.

EARLY EMBRYOGENESIS

After initial fertilization of two gametes, the resultant zygote undergoes a series of cell divisions. If this process occurs properly, the embryo ultimately implants within the endometrial wall of the uterine cavity. Pluripotent stem cells then begin to differentiate into three basic germ cell layers. By 22 days of gestation, the embryo is a disc-shaped structure containing the 3 germ cell layers: the ectoderm-lined amniotic cavity, the mesoderm, and the endoderm arising within the yolk sac. At the cranial and caudal ends, the ectoderm and endoderm are in direct contact, and these bilaminar areas are described as the oropharyngeal and cloacal membranes (Figure 22.1a) [1]. With further growth, this disc folds progressively both craniocaudally and laterally, resulting in yolk sac invagination. Over the ensuing 6 weeks, the yolk sac tubularizes and differentiates into the stomach, small intestine, and large intestine completing this process by week 10 of embryonic development [1]. During the course of this yolk sac tubularization, the intestines are extruded from the abdominal cavity by means of the incompletely developed anterior abdominal wall. Simultaneously with the abdominal wall closure, the developing intestine returns to the abdominal cavity and undergoes a 245° counterclockwise rotation around the superior mesenteric artery. This process is complete by 10 weeks of age and explains why the cecum is found in the right lower quadrant.

The development of the ureters, bladder, and urethra starts at the caudal end of the embryo at the cloacal membrane and within the adjacent mesenchyme. Via differential growth rates of the adjacent mesenchyme, the distal primitive hindgut begins to form a dilated chamber known as the cloaca. To appreciate the development of the lower urinary tract and female perineum, one must understand the transition from the 4 mm (4 weeks) to the 36 mm (10 weeks) embryo as the cloaca is partitioned into anterior (urogenital) and posterior (rectal) components.

DIVISION OF THE CLOACA

Following the invagination of the yolk sac at day 28, the primitive hindgut begins to form a dilated chamber, referred to as the cloaca. From this develops a ventral outgrowth orientated toward the umbilicus referred to as the allantois (Figure 22.2a). At this stage, the cloacal membrane that separates the internal cloaca (lined with endoderm derived from the yolk sac) from the external cloaca (composed of ectoderm) remains intact [2]. Part of the allantois will contribute to bladder development; those portions closest to the umbilicus will atrophy forming the urachus. However, in order for these structures to form, the internal cloaca must be partitioned into the ventral (urogenital) and dorsal (rectal) cloaca. This division of the cloaca begins during the fifth week within the upper portions of the chamber and is completed during the seventh week of gestation with resulting rupture of the cloacal membrane (Figure 22.2b) [2]. In classic descriptions from the 1800s, Rathke [3] claimed that this partition takes place by median fusion of two lateral ridges of the cloacal wall in a caudal direction, whereas Tourneaux [4] described a descending septum fusing with the cloacal membrane. By the beginning of the eighth week of gestation, the cloaca has been divided into anterior (ventral) and posterior (dorsal) components, and there is free communication between the internal and external cloacae due to the rupture of the cloacal membrane.

Several complex cellular signaling pathways are required for normal cloacal differentiation, which are being defined through the use of transgenic mice capable of labeling specific cell populations at specific time points. Using a murine model of fetal exposure to all-trans-retinoic acid on the ninth day of conception, Sasaki et al. [5] demonstrated that all fetal survivors had a short tail and imperforate anus. In females, this was manifest as a common cloaca in which the urethra, vagina, and rectum merged. The process of normal cloacal differentiation is under the control of the sonic hedgehog (Shh) signaling pathway (Figure 22.3a) [6]. Shh immunoreactivity was prominent in the rectal, urethral, and bladder epithelium in normal mice, but was absent in those with anorectal malformations (ARM). Bone morphogenetic protein type 4 (BMP4) immunoreactivity was noted in the mesenchyme below the epithelium staining for Shh expression in normal mice, but was absent in the population with ARM. In a second model using a knockout mouse model for Shh, Sukegawa et al. demonstrated that Shh signaling is critical to the concentric development of the hindgut [7]. Recent murine models demonstrate that Wnt5a and Axin2, both downstream of the Shh signaling, are absent in mice with ARM providing evidence of their importance in normal cloacal development [8]. Mice lacking two zinc finger transcription factors, Gli2 and Gli3, which participate in Shh signaling, display imperforate anus, rectourethral fistula, and anal stenosis [9]. Using a knockout mouse, Xu et al. provided evidence for an important role for BMP7 in the partitioning of the cloaca [10]. These BMP7 knockout mice demonstrated a persisting cloacal membrane that was associated with a hypoplastic rectum and a common urogenital sinus. Their data also show that deletion of BMP7 results in marked apoptosis of the cloacal endoderm (CE) (Figure 22.4). In addition, loss of BMP7 expression was associated with a failure of maturation of urethral keratin 8 into the keratin 14 isoform. The literature using these experimental models to delineate the molecular basis of the cloacal partitioning will expand as additional strains of genetically modified mice are available for study.

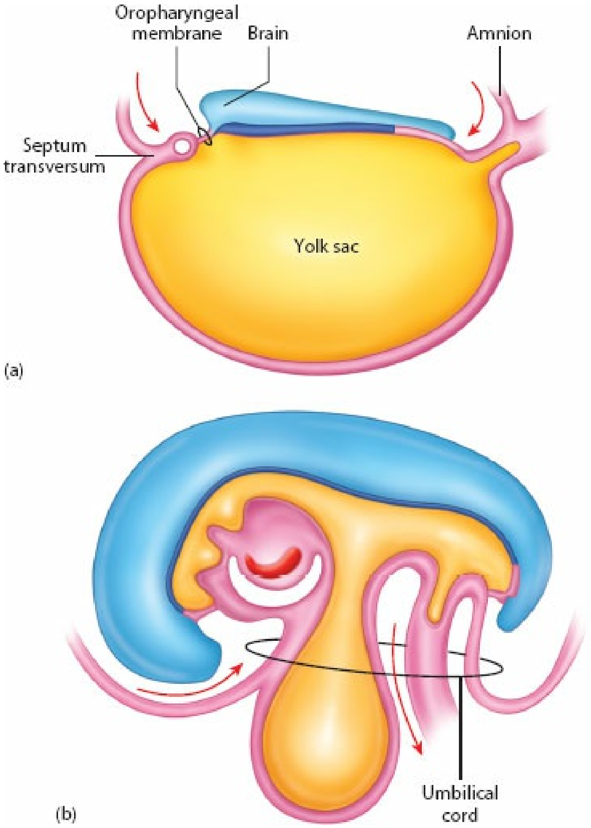

Figure 22.1 (a) Sagittal section of the discoid 22-day-old embryo, showing the relationship of the yolk sac to the neural and mesenchymal layers prior to the folding. The arrows show the direction of the subsequent folding that takes place by day 28. The oropharyngeal and cloacal membranes are already developing at the cranial and caudal ends of the neural tube. (b) Sagittal section of the embryo at day 28, showing the residual yolk sac contained within the developing umbilical cord. The second smaller extension of the yolk sac into the cord (which forms the basis of the allantois) can be seen. The cloacal membrane is just to the right of the umbilical cord. (Reprinted with permission from Stephens FD et al., *Congenital Anomalies of the Kidney, Urinary and Genital Tract*, 2nd ed., Martin Dunitz Limited, London, U.K., 2002, pp. 3–12, Fig. 1.1.)

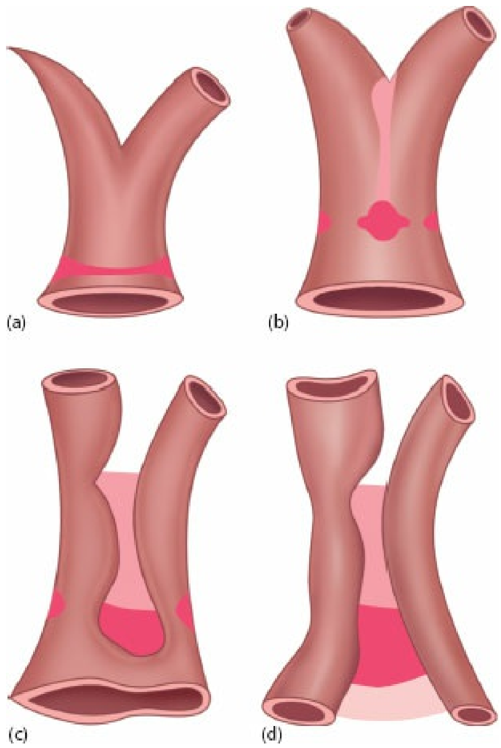

Figure 22.2 (a) Undivided internal cloaca at the 4 mm stage of development. The developing urorectal septum separates the allantois from the hindgut. The allantoic extension to the left leads to the umbilical cord and the future navel; this extension forms the basis of the urachal remnant. (b) Division of the internal cloaca is completed in this sequence, and the cloacal membrane has now ruptured, allowing for communication between the internal and external cloacal chambers. (c) With further growth, the external cloaca is partitioned by an extension of the urorectal septum and an ingrowth of the genital folds. (d) Fusion of the genital folds in the midline completes the separation of the urethra anteriorly from the rectum posteriorly. (Reprinted with permission from Stephens FD et al., *Congenital Anomalies of the Kidney, Urinary and Genital Tract*, 2nd ed., Martin Dunitz Limited, London, U.K., 2002, pp. 3–12, Fig. 1.2.)

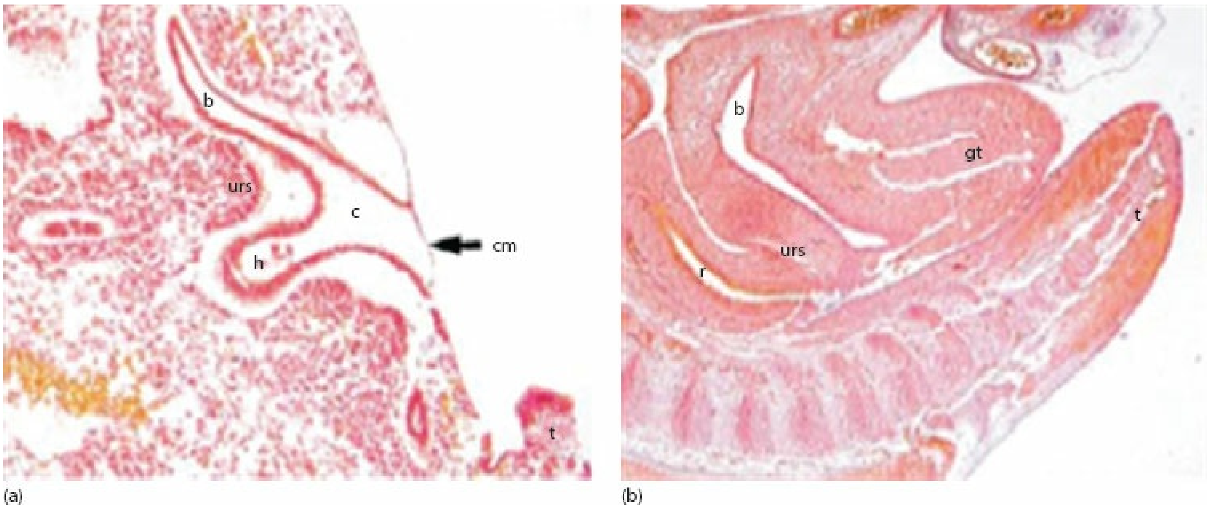

Figure 22.3 (a) Midsagittal section taken through a mouse embryo with a deletion of Shh expression shows a persistent cloaca covered by a thin cloacal membrane (cm). The bladder (b) and hindgut (h) are partially separated by the urorectal septum (urs). The proximal portion of the tail (t) can be seen. (b) In comparison a midsagittal section taken through a wild-type embryo showing almost complete separation of the bladder and urogenital sinus from the rectum (r). (With permission from Perriton CL et al., *Dev Biol*, 247, 26, 2002.)

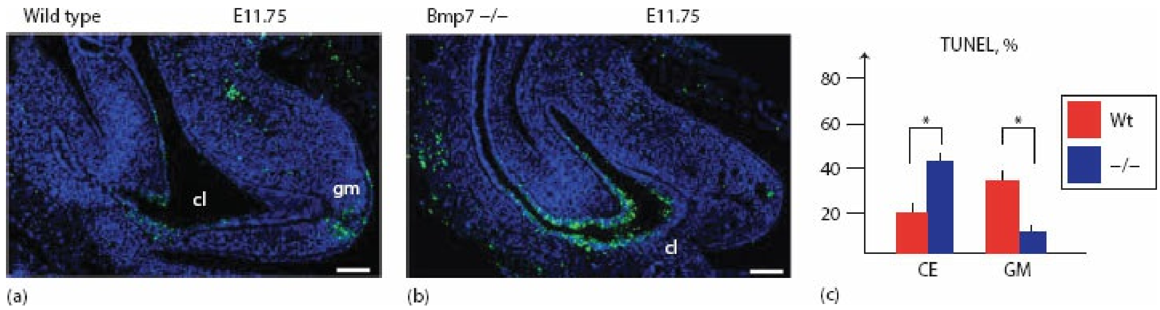

Figure 22.4 Bmp7 promotes cell survival in the cloacal endoderm (CE) as shown in sagittal sections of wild-type (a) and Bmp7-null (b) mice at E12.5. Zones of apoptosis were detected using a TUNEL assay (green fluorescence), and all nuclei were stained with DAPI (blue). (c) Graph shows the percentage of TUNEL-positive cells in CE and genital mesenchyme (gm). * indicates that $p < 0.05$ when comparing CE to GM. (With permission from Xu K et al., *PLOS ONE*, 7(1), e29372, 2012.)

Simultaneously with the septation of the internal cloaca, the external cloaca also undergoes partitioning in order for the normal perineum to develop and the process of external sexual differentiation begins. Partitioning of the external cloaca begins in part as a distal extension of the urorectal septum (Figure 22.2c) coupled to an inward migration of the genital folds to create the short female perineal body and median raphe (Figure 22.2d). In contrast, in males, the perineal body is elongated, and there is an anterior deflection of the proximal urethra, a process that is regulated by androgens. This phase also marks the onset of Müllerian differentiation in the female embryo.

Genital patterning is initiated 2 weeks prior to steroid synthesis in part through Shh-dependent signaling pathways. These concepts are nicely demonstrated in a mouse with a deletion of Shh expression; external genitalia are absent and a primitive persistent cloaca develops instead (Figure 22.3a) [6]. It appears that with Shh deletion, there is also a simultaneous downregulation of BMP2, BMP4, Fgf8, Fgf10, and Wnt5a, and increased apoptosis occurs within the genitalia [6]. Wang et al. studied the effects from the deletion of the *Six1* and *Six2* family of genes on perineal development [11]. These genes were strongly expressed in the pericloacal mesenchyme, and their deletion resulted in a urogenital sinus. They suggested that these genes program for an asymmetric growth pattern that leads to a narrowing of the cloaca that results in the perineal body. Some of the pathways must be androgen dependent of which ephrin B signaling in the developing urethral seam is one such example [12].

MÜLLERIAN DIFFERENTIATION

Primitive Müllerian ducts are present in both sexes during embryogenesis, but in males these involute due to the expression of Müllerian-inhibiting substance (MIS), which is secreted by the Sertoli cells of the testes. Mouse studies suggest the transcription factors Pax2, Pax8, Lim1, Emx2, Hoxa13, and Dach1 play a major role in Müllerian development. In Lim1-null mice, ovarian development still occurs but the female neonates lack uteri and fallopian tubes [13]. Other signaling molecules are postulated to be required for normal Müllerian development such as Wnt9b and Wnt4, which act via a paracrine mechanism [14] and retinoic acid [15]. Despite these findings in murine models, a study of 25 women affected by the Mayer–Rokitansky–Kuster–Hauser syndrome, characterized by varying degrees of uterine duplication or agenesis and renal findings, failed to support the role of Wnt4 and the retinoic acid receptor pathways [16]. These discrepancies between experimental and clinical observations are not surprising, because the genetic deletion in the mouse often targets the first step in a long complex cascade, whereas clinical syndromes may have defects much farther along in the same pathways.

By week 6, the Müllerian ducts form from the intermediate mesoderm located laterally to the Wolffian ducts and develop along the anterior–posterior axis of the embryo. Lineage tracing experiments in chicks and mice reveal that these ducts are all derived from different populations of coelomic epithelium without any direct cellular contribution from the adjacent Wolffian ducts [17]. Although cells derived from the Wolffian duct do not contribute to the Müllerian duct, cell–cell signaling between these ducts mediated by Wnt9b and Wnt4 induces Müllerian development. Indeed, close contact with the Wolffian duct is necessary for Müllerian duct elongation [18]. The Müllerian ducts begin as solid cords that likely tubularize on the basis of apoptosis during their differentiation.

Proximal parts of these ducts form the fallopian tubes; distally, they fuse in the midline producing the uterus, cervix, and proximal two-thirds of the vagina [19]. By week 7, the caudal ends of the Müllerian ducts migrate through the urorectal septum to penetrate the posterior aspect of the urethra [20] at the Müllerian tubercle between the two openings of the Wolffian ducts (Figure 22.5a) [19]. The urethra and Müllerian structures terminate in the common urogenital sinus (Figure 22.5b) prior to the separation of the urethra and vagina that proceeds as a result of differential growth (Figure 22.5c) and an anterior turn of the distal urethra (Figure 22.5d). Failures in distal migration of the Müllerian ducts to form the urogenital sinus may result in distal vaginal atresia.

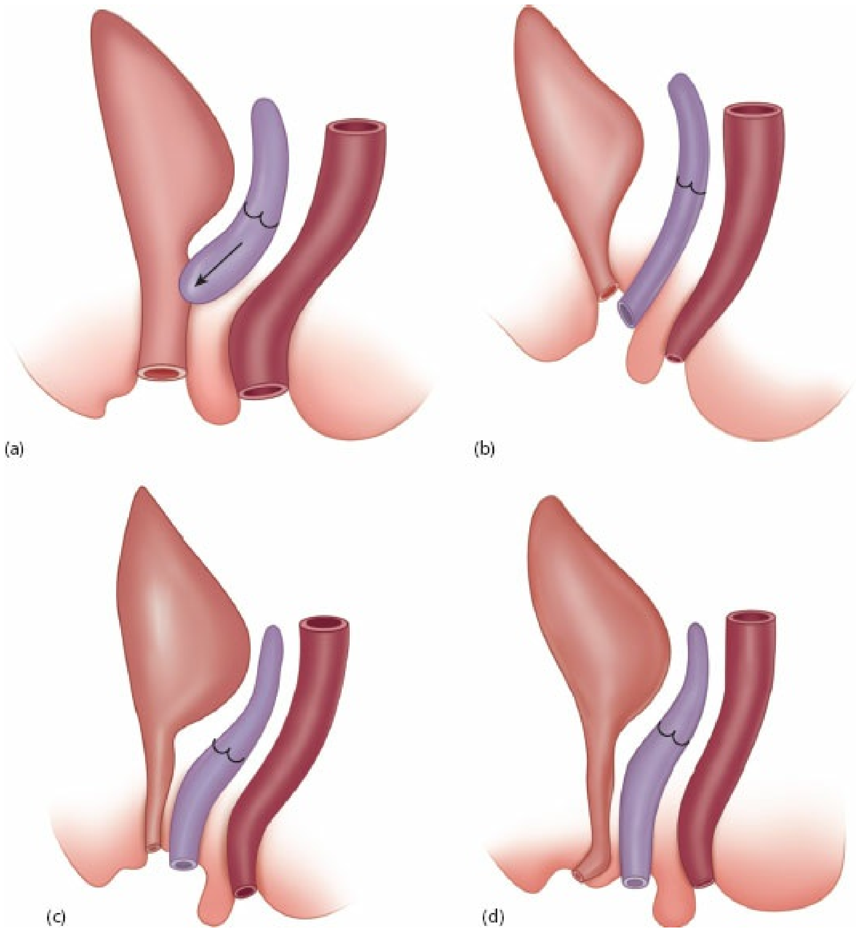

Figure 22.5 (a) The Müllerian ducts migrate to and penetrate the posterior urethra at week 7. The Müllerian ducts are guided to this point in the posterior urethra by the Wolffian ducts. (b) The ducts migrate caudally, and the urogenital sinus becomes a shallow channel. At this point, there is a good separation between the urethra and vagina. (c) With continued growth, the urogenital sinus disappears, as both the urethra and vaginal introitus are now at the perineal surface. The distal vagina is formed from sinus epithelium, which streams into the vaginal vault. (d) With continued growth, the urethra turns anteriorly to reach its final location. (Reprinted with permission from Stephens FD et al., *Congenital Anomalies of the Kidney, Urinary and Genital Tract*, 2nd ed., Martin Dunitz Limited, London, U.K., 2002, pp. 50–62, Fig. 4.1.)

It is important to appreciate the interaction between the Wolffian and Müllerian systems leading to formation of the urogenital sinus [21]. The Wolffian ducts serve to guide the Müllerian ducts to the urogenital sinus and are then carried toward the perineum in the lateral walls of the vagina and undergo involution in the course of normal differentiation. If the Wolffian ducts fail to involute properly, they can remain as small cysts within the lateral vaginal wall or the cervix that can enlarge, become infected, and present clinically as Gartner’s duct cysts. This embryology is also clinically relevant because the ureteral buds arise from the Wolffian system; as a result, the lateral walls of the vagina are a potential site for the rare insertion of an ectopic ureter.

DEVELOPMENT OF THE UROTHELIUM

The urothelium precedes development of the smooth muscle of the bladder wall and ureters. Within the ureter and the trigone, the urothelium has been postulated to arise from mesodermal origins. In contrast, the remainder of the bladder and proximal urethra are thought to arise from endodermal cell lines, whereas the distal urethra arises from ectoderm. Liang et al. have shown that urothelium derived from these distinct anatomic locations has unique patterns of expression of the uroplakins and keratins and that these are maintained in cell culture [22]. In addition, they showed that the urothelium undergoes squamous metaplasia in response to vitamin A deficiency, characterized by keratin expression restricted to the trigone and bottom half of the bladder. The key concept in this work is that the urothelium may look the same in these areas of the upper and lower urinary tract, but it is actually very heterogeneous.

SMOOTH MUSCLE DIFFERENTIATION

The connective tissue and smooth muscle of the urethra and bladder are subsequently derived from adjacent mesenchyme. The developing urethra and bladder contain no muscle in the early stages of development, and the endoderm of the urogenital sinus remains a single layer of epithelium up to the seventh week and then gradually assumes the appearance of transitional epithelium in the third month. The earliest muscle layers arise within the bladder, and the urethral smooth muscle layers are induced 1 week later implying that these smooth muscle bodies are distinct entities despite their close approximation at the bladder neck [23]. This should not be particularly surprising given the pharmacological differences and functional demands between these two intravesical regions of smooth muscle.

The mechanism by which epithelial mesenchymal interactions induce smooth muscle development has been described. Using fetal rat primitive mesenchyme grafted below the renal capsule in nude mice, Baskin et al. demonstrated that a transformation of this mesenchyme into smooth muscle was possible only if urothelium was also implanted simultaneously [24,25]. The growth factors, such as Shh, secreted by such epithelial regions are powerful driving forces for differentiation [26,27]. Further growth of smooth muscle is accompanied by complex serial changes in muscle-specific protein expression and cell turnover, as shown in a detailed study of mouse detrusor development [28].

DEVELOPMENT OF THE SPHINCTERS

Little data exist regarding the development of the internal, or smooth muscle, sphincter (i.e., the bladder neck). In contrast, more efforts have been expended in trying to better characterize the development of the striated external sphincter. Evidence supports the notion of transdifferentiation from smooth to striated muscle, which could then account for the development of the external sphincter [29]. As an alternative explanation, anatomic observations in female fetal specimens confirm that by 9 weeks of gestation, there is the condensation of undifferentiated mesenchyme immediately adjacent to the urethra. By 10 weeks of gestation, this mesenchyme has differentiated into striated muscle, which forms the omega-shaped external sphincter [30,31]. In this study, there was no evidence that concentric development of this striated muscle group is then followed by a selective loss of muscle to produce the omega-shaped characteristic of this sphincter. Similar observations were reported by Yucel and Baskin [32], who also noted that this striated sphincter is always distinct from the levator muscle group and commented on the innervation of this sphincter by both myelinated fibers and neurons that stained positively for nNOS [33]. A recent study examining 28 human female fetuses confirmed the presence of a discrete external urethral sphincter primordium at week 9 of gestation. Additionally, at week 15 the smooth sphincter and rhabdosphincter could be clearly identified. Both muscular complexes were located in the middle third of the urethra but only the muscle fibers of the smooth sphincter intermingled with the detrusor muscle [34].

DEVELOPMENT OF THE TRIGONE AND UPPER URINARY TRACT

The pronephros develops at the fourth week and differentiates into the mesonephric ducts and the mesonephros. The mesonephros consists of glomeruli and tubules, which open into the mesonephric (Wolffian) ducts derived from the pronephric ducts. The mesonephric ducts extend caudally and drain into the cloaca [1], and an outgrowth of the ducts near their insertion at the cloaca gives rise to the ureteral buds (Figures 22.6 and 22.7) [35,36]. The ureteral buds grow cranially until they contact the metanephric mesenchyme at which point a series of complex reciprocal interactions between the bud and the mesoderm result in differentiation to the metanephros and ultimately a functioning kidney; fetal urine production is evident by the ninth week of gestation. The initiation location of the ureteral bud is critical for the formation of the trigone, the development of a normal vesicoureteral junction, and ultimately the formation of a normal kidney. In 1975, Mackie and Stephens [37] proposed the ureteral bud hypothesis that stated that a bud arising from an abnormal location along the Wolffian duct would lead to abnormal nephrogenesis (Figure 22.8) [38]. They proposed that if the bud appeared too close to the cloaca, it would ultimately be incorporated into the trigone in a very lateral position leaving it more prone to reflux, and in extreme cases, abnormal nephrogenesis would occur. Clinically, this might become apparent in the neonate who presents with antenatally diagnosed hydronephrosis, who in the first days of life undergoes a VCUG demonstrating high-grade reflux and who on sonography has abnormal renal parenchyma and an elevated creatinine. They also noted that if the bud arose too far away from the cloaca, it would be carried out into an ectopic position either within the bladder neck, the urethra, or even the lateral walls of the vagina in females. Many of these ectopic ureters are associated with a small volume of dysplastic renal parenchyma.

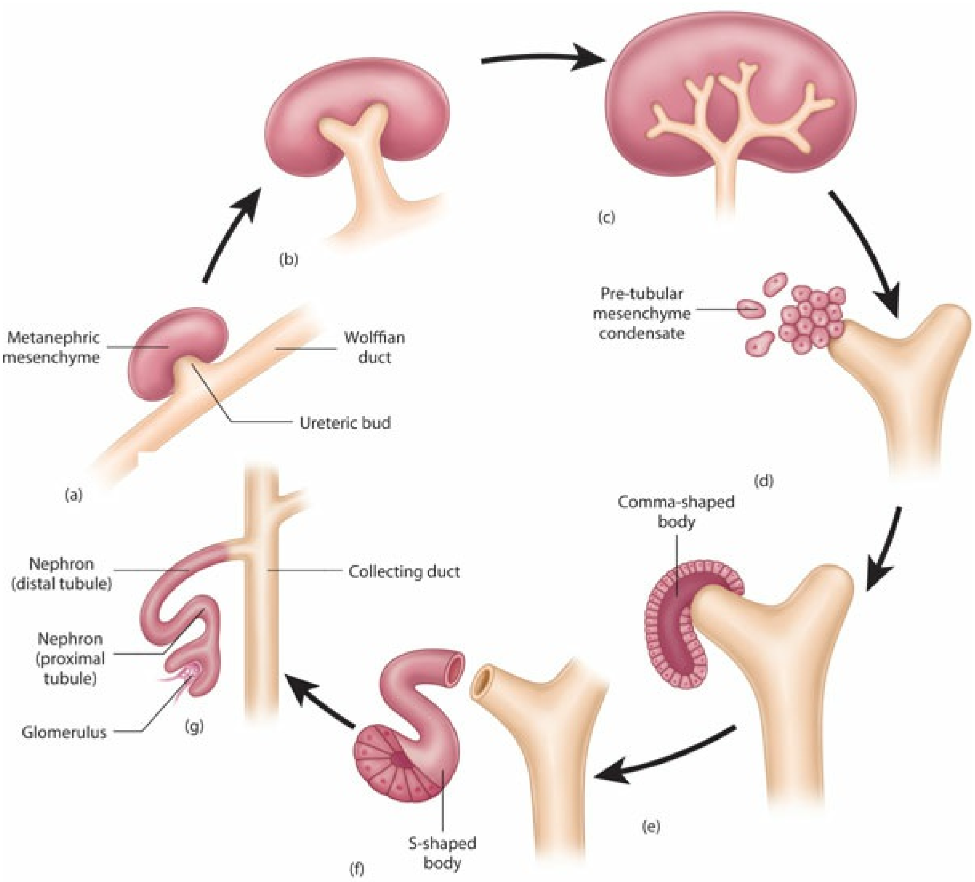

Figure 22.6 Stages of the renal branching morphogenesis: (a) Ureteral bud outgrowth from the Wolffian duct is induced by signals from the metanephric mesenchyme. (b, c) Invasion of the metanephric mesenchyme by the ureteral bud results in branching. (d) At the tips of the branches, the epithelium induces the mesenchyme to form pretubular aggregates, which are stimulated to undergo mesenchymal to epithelial transformation through the formation of comma-shaped (e) and S-shaped (f) bodies to form components of the nephron. (g) The renal tubules merge with the epithelial and vascular components of the glomerulus. (With permission from Shah MM et al., *Development*, 131, 1449, 2004.)

Normal trigonal development is essential to the prevention of vesicoureteral reflux, a common clinical entity in young girls. Its embryological origins remain a source of debate as the trigone was traditionally thought to be of mesodermal origin deriving from the common nephric duct and the ureter [39]. In order for the ureteral bud to become incorporated into the developing urogenital sinus, the common nephric duct must become absorbed into this sinus. Thus, it would stand to reason that at least part of the trigone is of mesodermal origin. Others have postulated that the detrusor muscle contributed to the trigone [40]. Indeed, recent studies using transgenic mice suggest that in fact the trigone is of endodermal origin [41]. Examination of murine models has demonstrated that the majority of the trigone is derived from detrusor muscle but interdigitating ureteral fibers do contribute to the final trigonal structure. These data were obtained via immunohistochemical analysis of both murine and human fetal tissue [42]. Apoptosis plays an integral role in trigone formation; the common nephric duct undergoes apoptosis resulting in separation of the ureter from the Wolffian duct and apoptosis is required to create a patent ureteral orifice [43–45]. It is also likely that the final position of the ureteral orifice also depends on the growth of the bladder itself [46].

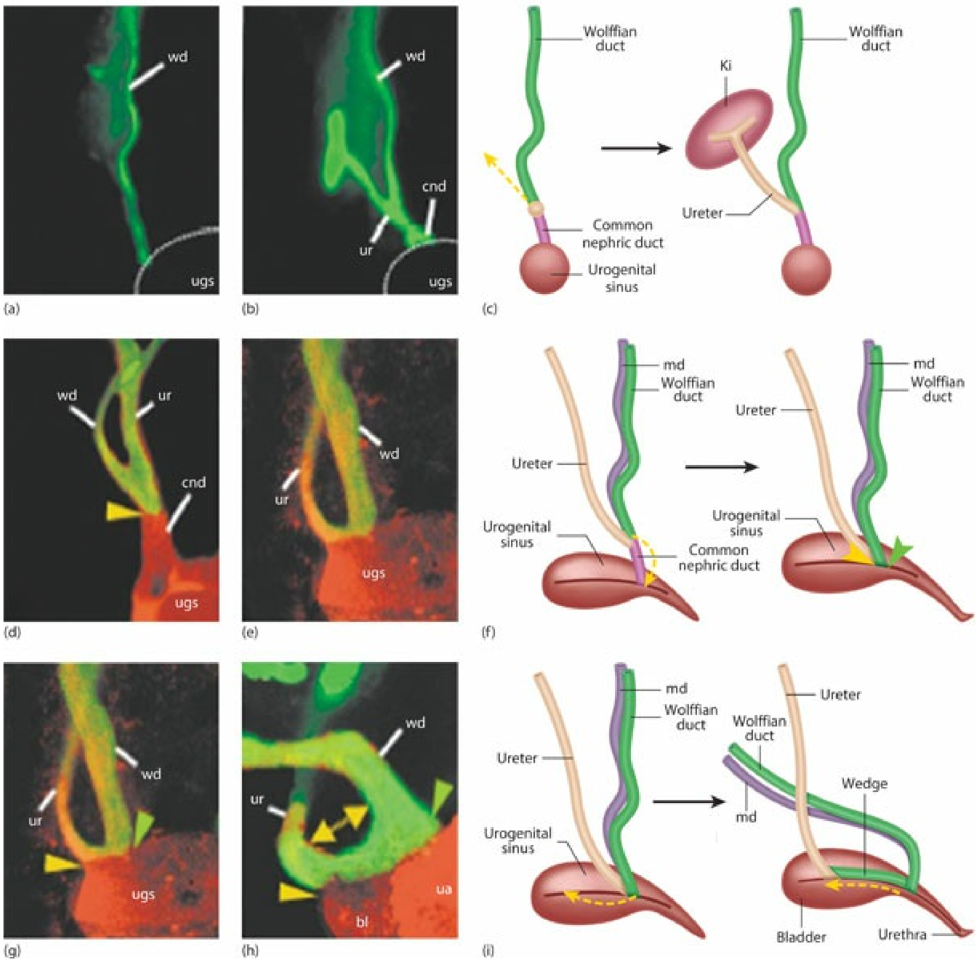

Figure 22.7 Visualization of the three stages of ureter maturation in vivo in Hoxb7-GFP mice that express green fluorescent protein in epithelia of the fetal excretory system. (a–c) Ureteral bud formation and outgrowth: The distal ureter (ur) remains attached to the Wolffian duct (wd). The distal ureter starts to separate from the primitive bladder (ugs) by a terminal Wolffian duct segment, the common nephric duct (cnd). (d–f) Vertical displacement: The distal ureter descends and contacts the urogenital sinus. The yellow arrow indicates the common nephric duct. Broken yellow arrow shows the downward movement of the ureter toward the urogenital sinus. Yellow and green arrows indicate the final position of the distal ureter and Wolffian duct. (g–i) Lateral displacement: The distal ureter separates from the Wolffian duct and moves to the final position at bladder base. Yellow and green arrows mark the position of the distal ureter and Wolffian duct before and after separation. Double-headed yellow arrow indicates epithelial wedge, an epithelial outgrowth, which facilitates the separation. Color code for (c, f, i): Wolffian duct and trigonal wedge, green; urogenital sinus, grey; Müllerian duct, pink; common nephric duct, red; kidney and ureter, blue. (With permission from Batourina E et al., *Nat Genet*, 32, 109, 2002.)

The kidney develops as a result of complex reciprocal signaling between the ureteral bud and the primitive metanephric mesenchyme [47,48]. Once this signaling is initiated, the bud elongates to penetrate the blastema, and the process of branching begins. In order for the final form of a single human kidney to have 500,000 to 1 million nephrons, the ureteral bud must undergo branching morphogenesis (Figure 22.6) [28]. Iterative branching of the ureteral bud must occur about 15 times during human development in order to lead to this number of nephrons. As this division of the terminal ureteral bud takes place to produce a treelike structure, lateral branches differentiate into terminal bifid branches. In these terminal bifid branches, the ureteral bud tip will attach itself to a nephron and remove itself from further bifurcations. This attachment of the bud to a primitive nephron then initiates the formation of a full nephron. Critical to this view is the notion that the final population of nephrons is ultimately determined by the branching and proper functioning of the ureteral bud, a view espoused by Mackie and Stephens over 30 years ago [37]. Equally critical to establishing normal renal function are the acquisition of the renal artery(ies) and subsequent vascular development (for a more detailed review of renal development, the reader is referred to Shah [47]).

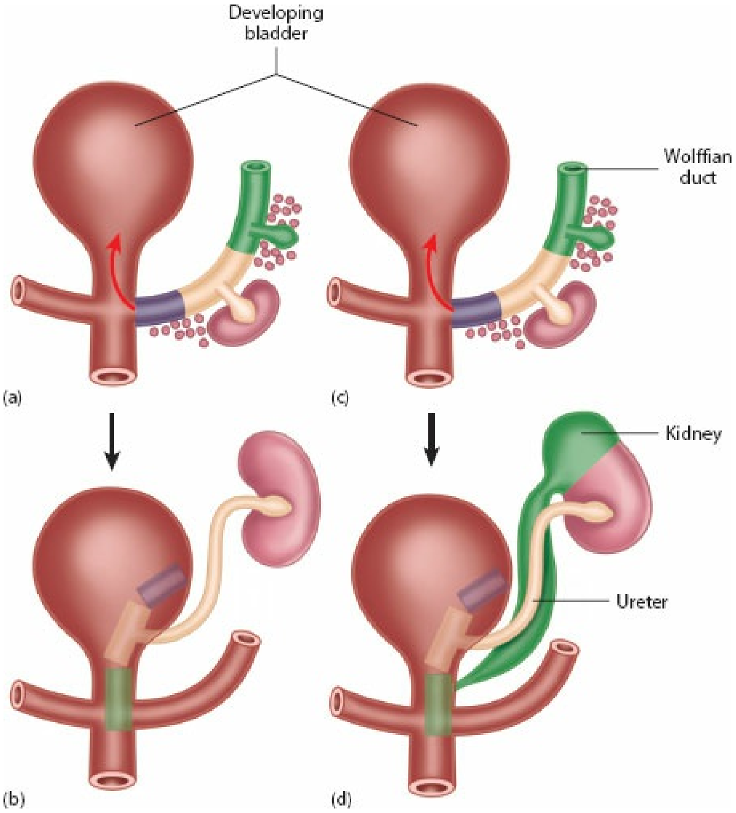

Figure 22.8 The ureteral bud hypothesis described by Mackie and Stephens [38]. (a, b) Normal kidney development: Single ureteral bud is induced and grows into the nephric mesenchyme (small dots). The caudal end of the Wolffian duct is incorporated into the developing bladder (red arrow). The yellow-marked region contributes to the trigone, the green one to the urethra, and blue for the lateral bladder. (c, d) Ectopic ureter development: A second, ectopic ureteral bud is induced more anteriorly than normal (green region at Wolffian duct) and interacts with the adjacent nephrogenic mesenchyme giving rise to a duplex system. This ectopic ureter opens into the urethra with the abnormal outflow and development of hydroureter. (With permission from Kume T et al., *Development*, 127, 1387, 2000.)

With current methods of molecular biology, the complex chemistry underlying these reciprocal interactions is being clarified, and several examples are offered here. Transcription factor PAX2 is expressed during normal kidney development and activates Wnt4 gene expression. PAX2 knockout mice are anephric, while a heterozygous PAX2 mutation results in a 60% decrease in Wnt4 mRNA [49]. In vitro studies have shown that glial cell–derived neurotrophic factor (GDNF) secreted by the metanephric mesenchyme serves to induce ureteral budding [38]. This is supported by the observation that the ureters and kidney do not develop in GDNF knockout mice. It has also been shown that gene products that antagonize GDNF expression such as FOXc1 (Figure 22.9) [38] or BMP4 [50] can result in multiple bud formation and duplex collecting systems. There is also a role for retinoic acid–mediated signaling in the development of the ureteral buds and trigone as shown in a model using targeted deletion of the retinoic acid receptors [36]. Abnormal vesicoureteral development has also been demonstrated in the presence of targeted RET overexpression [51] or the deletion of the type 2 angiotensin receptor [52].

GROWTH OF THE BLADDER

With the development of the trigone and the sphincter complex, the bladder can begin its cycle of filling and emptying. This is crucial for normal development since fetal urine serves as amniotic fluid, which is essential for normal lung development. However, bladder cycling is also crucial for development of bladder capacity. Experimental, as well as clinical, evidence supports this concept. In experimental work in a canine model of urinary diversion, Chun et al. [53] showed that with diversion, the bladder mass declined, as did muscarinic receptor density and the bladder's response to pharmacological agonists. These proved to be reversible upon reimplantation of the ureters into the bladder. Matsumoto et al. demonstrated that ureteral diversion in the fetal sheep resulted in a smaller bladder with poor compliance and diminished responses to pharmacological agonists [54]. Urinary diversion in the fetal sheep model was also associated with altered patterns of collagen expression [55] and decreased cell proliferation and apoptosis [56] in the bladder wall. Thus, there is ample support for the concept that mechanical distention is an essential contributor to normal bladder development. This is supported by the clinical observations in patients with bilateral ectopic ureters and bladder exstrophy, which are two conditions in which the bladder wall fails to cycle. Both conditions are characterized by small-capacity bladders and poor wall compliance.

INNERVATION

The common origins of the bladder and rectum from the cloaca are also reflected in their patterns of innervation. Contraction of the bladder is mediated by the pelvic nerve that arises from the sacral segments $S_{2,3,4}$. Sensory fibers from the bladder are also directed to these same sacral segments. Given their common embryological origins, it is not surprising that sensory fibers from the rectum are also directed to the same segments. Experimental work done in rat models using viral vectors expressing red or green fluorescent proteins has shown that there is a cross talk between these two organ systems. As an example using modified pseudorabies virus tagged to express green fluorescent protein injected into the bladder and the modified pseudorabies virus tagged to express beta galactosidase in the rectum, Rouzade-Dominguez et al. [57] showed that Barrington's nucleus receives innervation from both systems (Figure 22.10). Many of the nuclei in Barrington's nucleus were stained either green (reflecting sensory input from the bladder) or red (reflecting sensory input from the rectum because the beta galactosidase was visualized with an antibody tagged with red fluorescent protein). However, when imaged under dual fluorescent conditions, a substantial fraction of these nerves stained yellow *indicating that these individual nerves were receiving sensory input from both the bladder and the rectum*.

This image is of clinical relevance because constipation is a major contributing factor to bladder dysfunction because it can affect both the sensory and motor pathways. Evidence for this comes from ample clinical observations that children with incontinence improve following treatment of their underlying constipation [59]. Further evidence comes from a clinical study of women undergoing urodynamic evaluations in which a balloon catheter was placed in the rectum; the results of the urodynamic parameters varied substantially once the balloon was inflated to mimic the rectal distention seen with constipation [60]. Using an experimental approach in the rat, Miyazato et al. were able to show that rectal dilation with a balloon increased the intercontraction interval and diminished the detrusor pressure and that these changes were mediated by glycinergic and GABAergic mechanisms [61].

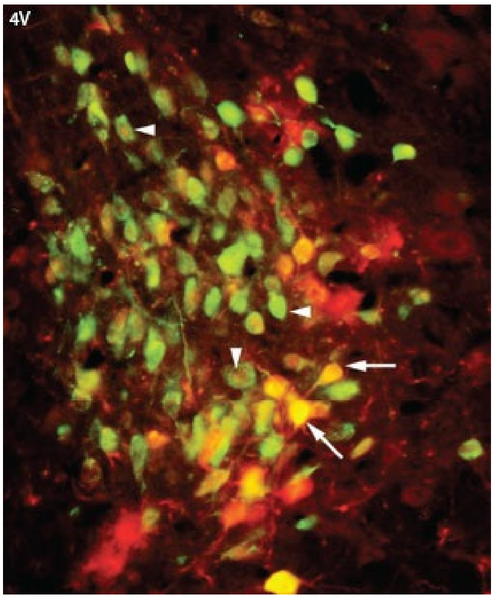

Figure 22.10 Dual fluorescent microscopy of Barrington's nucleus in a rat. These neurons were labeled with pseudorabies virus expressing green fluorescent protein that was injected into the bladder (green) and pseudorabies virus expressing β-galactosidase (red) that was injected into the distal colon. A substantial population of these neurons are labeled with both viruses appearing as either yellow or orange (arrows) or cells that have a red nucleus and green cytoplasm (arrowheads). CLINICAL APPLICATIONS

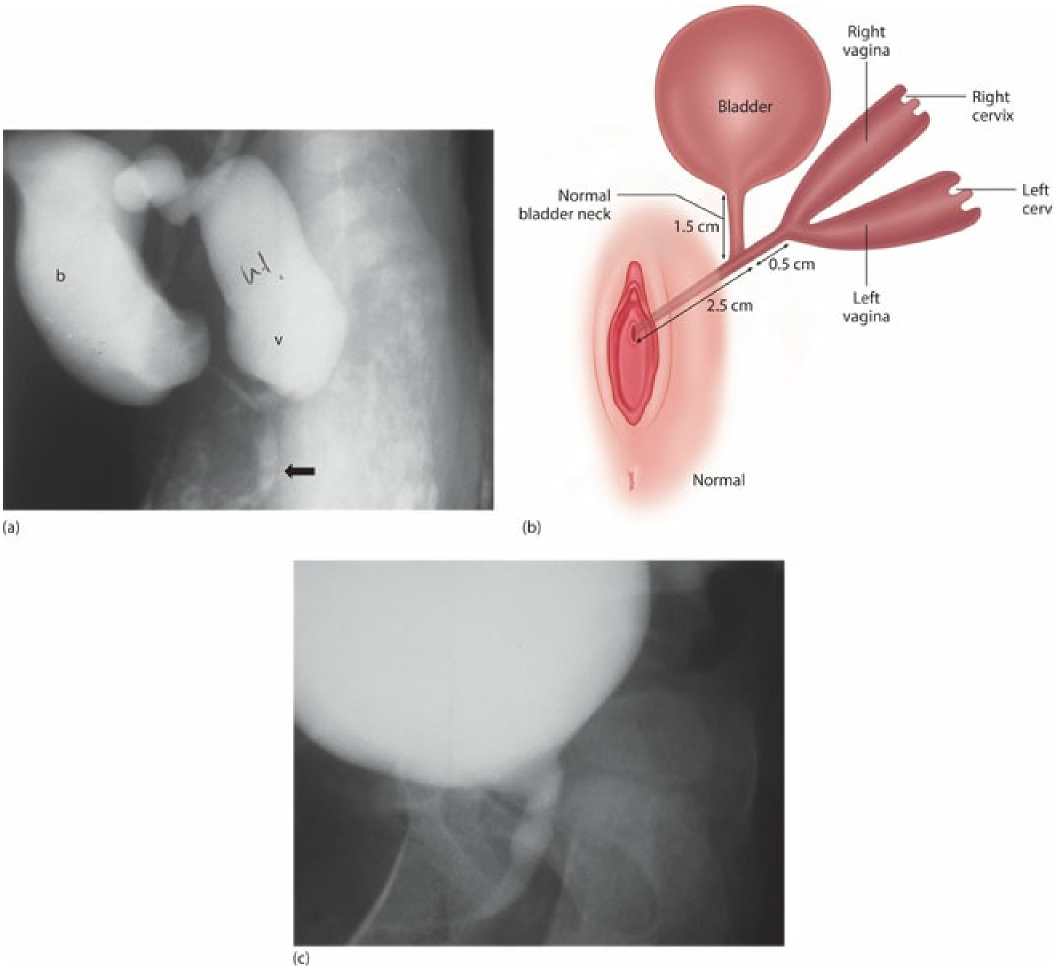
Urogenital Sinus

Persistence of the urogenital sinus can occur as an isolated malformation or in association with other conditions such as congenital adrenal hyperplasia. In these patients, the urethra and the vagina converge in a short common channel, and the convergence is close to the perineum. In some cases, the voided urine is trapped within the vagina, resulting in hydrocolpos. These patients may present with a palpable pelvic mass requiring decompression, infection of obstructed urine, or overflow incontinence. The rectum is often displaced anteriorly, but it functions normally. A review of Figure 22.5 should allow the reader to understand the embryological basis for this anomaly. The distal Müllerian ducts fuse with the urethra and then migrate caudally during normal perineal development. Arrest of this distal migration at any point will result in a urogenital sinus as the fused urethra and vagina drain into a common channel. On physical examination, the vaginal introitus is absent with a single opening in the urethral position, although the labia majora and minora might be normal in appearance. Urogenital sinuses are usually separated into those with a low confluence, or short common channel, and those with a high confluence, or long common channel. Separation into these two categories dictates the type of surgical repair that can be performed. The distance from the bladder neck to the confluence is also paramount in determining the surgical technique and outcome [62].



(a) (b)

(c)

Figure 22.11 (a) Genitogram demonstrating a common urogenital sinus (arrow) dividing into the bladder (b) and dilated vagina (v). (b) Summary of the anatomy as revealed by endoscopic examination. (c) Postoperative result after reconstruction and conversion of the urogenital sinus into urethra.

The diagnosis of a urogenital sinus is confirmed radiographically with a retrograde contrast injection, i.e., a genitogram (Figure 22.11a). If the genitogram is inconclusive and does not reveal the level of confluence, a cystoscopy and retrograde contrast study should be performed. Depending on the length of the common channel and the complexity of related malformations, different surgical procedures are available. The objectives of the surgical repair are (1) the separation of urogenital tract to allow for normal voiding and (2) the creation of an adequate vaginal introitus. A urogenital sinus with a low confluence can be managed with a "cutback" operation combined with an inverted U-flap to widen the introitus to prevent stenosis [63]. When the common channel exceeds 3 cm, the modified total urogenital sinus mobilization is the preferred approach [64,65]. This technique avoids separation of the urethra from the vagina and circumferentially dissects the urogenital sinus as a single unit. The urogenital sinus mobilization technique has been modified since the original description. Rink and colleagues advocate utilizing the mobilized sinus tissue to create a mucosal vestibule or a posterior vaginal flap [66]. Additionally, the same group has described a partial urogenital mobilization that limits dissection to remain distal to the pubourethral ligament in hopes of avoiding dissection around the innervation of the urinary sphincter and clitoris [67]. Once the urogenital sinus has been mobilized distally, a perineal flap can be introduced into the posterior wall of the vagina providing a normal caliber vaginal opening. Depending on the length of the common channel and related anatomic malformations, a more complex surgical repair may be necessary [68,69].

Case: A 1-day-old female was noted to have a palpable mass in her lower abdomen, and sonography revealed distended fluid-filled collections in her pelvis. On physical exam, her lower abdomen was filled with a tense mass, the rectum was normally placed, but no vaginal opening could be appreciated. Via the one opening near her introitus, a genitogram was performed (Figure 22.11a), demonstrating a common UG sinus with a bifurcation leading to the bladder and a dilated vagina. A subsequent endoscopic examination revealed the anatomy shown in Figure 22.11 and allowed for a plan of reconstruction to be developed. Using a posterior sagittal approach, the urethrovaginal trifurcation was divided, and the urogenital sinus was converted into the urethra. The duplex vaginas were then mobilized and moved down into the perineum with a perineal skin flap to complete the vaginoplasty.

Common Cloaca

Rarely patients may present with a common cloaca in which the urethra, vagina, and rectum converge into one common sinus that exits at the perineum. Many of these patients often present with the associated findings of spinal cord tethering and a neurogenic bladder. The association of these anomalies was initially described in 1961 by Duhamel and termed caudal regression syndrome [70]. As the somites develop from cranial to caudal during early gestation, it is possible that an isolated cloacal anomaly represents a late defect in somite development and a milder form of caudal regression syndrome. Rodent models have demonstrated that the known teratogen retinoic acid can result in spina bifida, imperforate anus, genitourinary anomalies, omphalocele, and limb abnormalities when administered on gestational day eight (equivalent to gestational week four in humans) [71,72]. In contrast, the administration of the same teratogen on gestational day nine results in anal atresia, urethral atresia, and tail deformities providing evidence that these anomalies are part of a spectrum [73]. An example of this association may be found in patients with the VACTERL (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, esophageal atresia, renal anomalies, radial/limb anomalies) syndrome.

Congenital Vaginal Anomalies

Though rare, a variety of congenital vaginal anomalies have been described in the urological and gynecological literature. Such anomalies include transverse vaginal septum, vaginal duplication, distal vaginal atresia, and vaginal agenesis. Increasingly these diagnoses may be made in the neonatal period because of the widespread use of prenatal sonography. Ultrasound can reveal hydrocolpos, duplications, or associated anomalies, such as unilateral renal agenesis, which raise suspicion for a vaginal anomaly. But many vaginal anomalies will only become apparent with the onset of puberty. A thorough medical history and physical examination in conjunction with pelvic ultrasonography and magnetic resonance imaging can usually determine the exact diagnosis [74]. The constellation of vaginal agenesis, or the absence of the proximal vagina, and unilateral renal agenesis is the classic description of Mayer–Rokitansky–Kuster–Hauser syndrome [19]. This association between anomalies of renal and vaginal development can be related to the complex relationship between the Wolffian ducts and Müllerian ducts (Figure 22.5). Disturbances in the paracrine signaling required for the normal development of the genitourinary tract in women can likely result in abnormal renal and vaginal development. Thus, a condition in which ipsilateral and/or bilateral vaginal agenesis or stenosis is associated with unilateral renal agenesis is not surprising.

Case: A previously healthy and normally developed 12-year-old female presented with multiple 1-week episodes of abdominal pain occurring on a monthly basis; she was amenorrheic. Breast development was present as was pubic hair, and the urethra was normally placed above a blind-ending vaginal introitus. Further imaging with ultrasound and MRI revealed a huge hematocolpos with dilated fallopian tubes on both sides (Figure 22.12) without any other malformations of the upper or lower urinary tract. Evaluation under anesthesia revealed a complete distal atresia of the vagina; the vaginal to perineal surface distance was measured at 10 cm. She was managed with a combined laparoscopic mobilization of the proximal vagina, with a simultaneous perineal exploration and vaginal pull-through in combination with a perineal skin flap.

The normal urethral development seen in this case illustrates the concept that there was most likely a failure of fusion between the distal Müllerian ducts and the urethra (Figure 22.5) [20]. Subsequently urethral migration proceeded distally leaving the distal Müllerian remnants in a position far from the perineal body. Normal urethral migration to the perineum is also seen in patients with androgen resistance syndromes despite the absence of the upper two-thirds of the vagina, uterus, and fallopian tubes.

Ectopic Ureter

A ureter that opens anywhere outside of the trigone is considered ectopic and is the result of a displaced ureteral bud. Ureteral buds that develop very low along the mesonephric duct will be sited in a laterocranial ectopic position, often associated with a significant vesicoureteral reflux. In contrast, if a bud develops high along the mesonephric duct, it bypasses the trigone and inserts within the urethra, vestibule, or vagina. An ectopic ureter can drain a single system [75], but about 70% are associated with complete ureteral duplication with the ectopic ureter draining the upper moiety of a complete pyeloureteral duplication. Complete ureteral duplication occurs when two separate ureteral buds arise independently from the mesonephric duct. A duplex kidney is induced when these two buds meet the metanephric blastema. During the development of the trigone, the most cranial ureter that drains the upper moiety of the duplex kidney rotates inwardly on its long axis and crosses the lower pole ureter. A normal duplex kidney develops, if the two ureters originate close to each other and both ureteral orifices terminate on the trigone. However, if the ureteral buds arise from widely separate positions on the mesonephric duct, the upper pole ureter is incorporated into the urogenital sinus at a later stage of development, and the resulting orifice is situated in an ectopic position, inferior to the trigone. This accounts for the Meyer–Weigert law that states that the upper pole ureter shall always be found distal to that ureter, which drains the lower renal unit. Mackie and Stephens [37] have postulated that induction of the metanephric blastema either too caudally or too cranially along the metanephric blastema will result in renal dysplasia. This is the reason for impaired renal function of the renal unit draining into an ectopic ureter, whereas refluxing ureters most often drain normally functioning renal units.

(c)

Figure 22.12 (a) Pelvic ultrasound (sagittal) demonstrating the blood-filled vagina (v) behind the bladder (b). (b) MRI furthermore revealed dilated fallopian tubes (f) on both sides. (v) Vagina, (u) uterus. (c) MRI in coronal view.

If the ureter opens below the internal sphincter, the patient with such an ectopic ureter can present with incontinence. If the ureteral bud arises very high along the mesonephric duct, it fails to become incorporated into the lower urinary tract and remains confluent with the mesonephric duct. These vestiges of the mesonephric system track along the lateral vagina wall and may become clinically manifest as Gartner’s duct cysts. This also provides an embryological basis for the rare vaginal ectopic ureter. Approximately one-half of female patients with ectopic ureters present with continuous dribbling of urine, despite normal bladder emptying due to the normally situated ipsilateral or contralateral ureteral orifices [75,76]. If the ectopic ureter is draining a dysplastic or hypoplastic kidney or upper pole, infection or vaginal discharge may be the only complaint. Today, most of these cases are diagnosed by prenatal ultrasound, since most ectopic ureters are associated with significant hydronephrosis. On occasion, this diagnosis is not established before toilet training and some patients are mistakenly diagnosed with voiding dysfunction.

The traditional imaging workup included a cyclic VCUG, which demonstrates reflux into the ectopic ureter in 70%–80% of cases, and an IV urogram or CT scan. More recently, the application of MR urography has provided a global view of the malformation, including renal dysplasia and dilated ureter, even in the presence of diminished renal function, thus making it a gold standard [77]. Depending on renal function, the treatment varies from ureteroureterostomy in duplicated systems, upper pole resection with or without ureterectomy, various ureteroneocystostomy procedures, or nephroureterectomy.

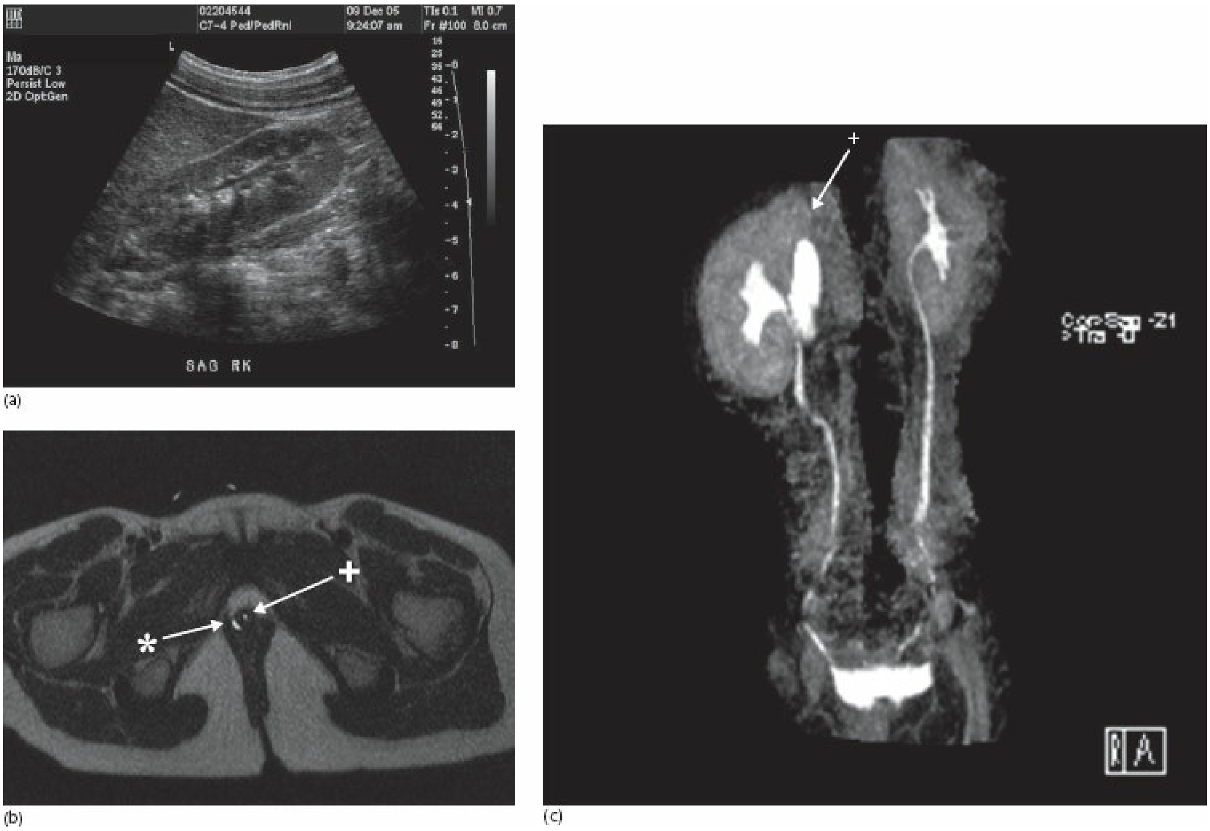

Figure 22.13 (a) Renal ultrasound demonstrating a normal right kidney with no signs of a ureteral duplication. (b) Transverse pelvic images showing the insertion of the ectopic ureter (*) into the urethra adjacent to the Foley catheter (+) placed at the time of the MRI urogram. (c) Coronal sections of the abdomen on MRI showing a ureteral duplication (+). At surgical exploration this ureter was found to connect with a tiny remnant of renal parenchyma.

Case: A 7-year-old female presented for the evaluation of continuous urinary incontinence. A renal bladder ultrasound ordered by her pediatrician was reviewed and found to be normal. She voided at regular intervals and was not constipated. A voiding log confirmed her good voiding habits, and a urinary flow rate revealed a normal bell-shaped curve with no residual urine as determined by office sonography (Figure 22.13). An MRI urogram was obtained, which confirmed the presence of a small upper pole duplication associated with an ectopic ureter to the urethra. Following upper pole partial nephrectomy, she reported immediate continence of urine.

In rare instances, bilateral ureteral budding may occur at a cranial location along the mesonephric duct and result in bilateral ectopic ureters. These patients present with total urinary incontinence, a deficient internal sphincter, and a noncompliant bladder with small capacity. These cases serve to illustrate the importance of early bladder cycling for the acquisition of normal capacity and compliance, a concept that has been confirmed in fetal experimental models [55]. For these patients, urinary continence will require complex surgery most often consisting of a bladder neck reconstruction, ureteral reimplantation, and augmentation.

Gartner's Duct Cyst

Remnants of the Wolffian ducts may be found in the lateral vaginal wall and may become clinically apparent if they swell or become infected. If these rupture, and if there is enough poorly functioning renal parenchyma associated with the system, the patient will be left with a continuous low-grade incontinence.

Case: A 4-month-old female presented with a prenatal history significant for an ultrasound, which demonstrated an absent right kidney. At the time of this presentation, she had 2 cm cystic structure within her labia that was covered by a thin membrane (Figure 22.14). An ultrasound showed a solitary left kidney and no evidence of a ureterocele, and a VCUG showed high-grade reflux into the left kidney. The MRI showed a solitary left kidney and an ectopic remnant of a right kidney (Figure 22.14c) that was associated with a cystic dilation, which ultimately was traced into the right wall of the vagina and led to the cystic mass seen on physical examination (shown from the posterior projection in Figure 22.14). The cyst was decompressed by endoscopic incision and marsupialization into the vagina in order to prevent infection. However, her reflux persisted and the family reported her perineum was consistently wet. At 2 years of age, she underwent a robotic left ureteral reimplant and a right nephrectomy of the atrophic dysplastic kidney. The family now reports a dry perineum.

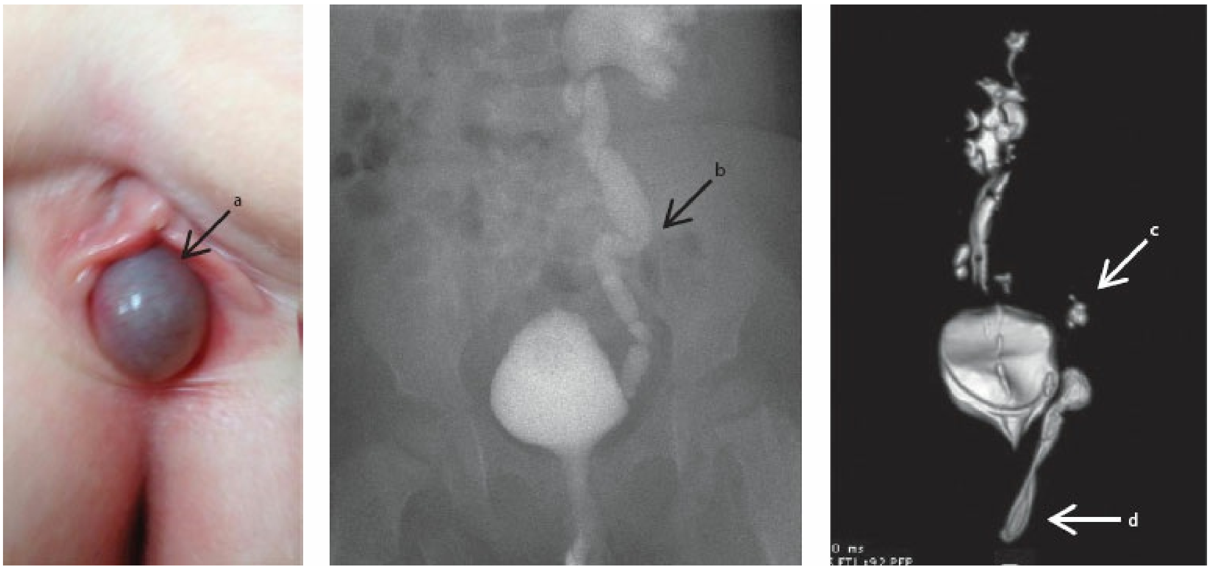

Figure 22.14 This 3-month-old infant female presented with a bulging mass within her labia (a) and a history of antenatal sonography showing a solitary kidney. A renal bladder ultrasound (not shown) confirmed that she had a solitary left kidney into which there was high-grade vesicoureteral reflux as shown on a VCUG (b). An MRI with a three-dimensional reconstruction was performed and rotated to demonstrate the posterior view. This revealed a solitary right kidney with a duplication and a small atrophic remnant of primitive renal tubules on the left (c). This dysplastic left kidney could be traced to the Gartner's duct cyst, which traveled in the lateral right vaginal wall (d).

Ureterocele

A ureterocele is a cystic dilation of the lower end of the ureter, which protrudes into the bladder. The origin of the defect begins in the eighth week of gestation. This anomaly has been attributed to a failure of Chwalle's epithelial membrane to regress during the incorporation of the ureteral bud into the developing trigone [78]. Ureteroceles are associated with duplex systems in 80% of cases, and girls are affected four times more frequently than boys [79,80]. Since most ureteroceles are associated with hydronephrosis, the vast majority of these patients are now being diagnosed with antenatal ultrasound [81]. Prenatal diagnosis and early postnatal management of duplex-system ureteroceles are beneficial to decrease morbidity and potential adverse outcomes related to infection [82]. Clinically, ureteroceles are the most common cause of urinary retention in female infants [83].

The initial workup of these patients should include a renal and bladder ultrasound, a voiding cystourethrogram to detect whether there is associated reflux, and a renal scan to determine the functional contribution of the system (especially in the case of the rare single-system ureterocele). Patients with ureteroceles have a high incidence of associated vesicoureteral reflux into the ipsilateral lower pole and less commonly the contralateral collecting system [84]. The presence or absence of reflux may affect the type of surgical intervention performed and therefore must be established. A large number of options exist for management of these patients: complete upper and lower urinary tract reconstruction, upper pole heminephrectomy (simplified approach) and ureterocele decompression, and endoscopic incision [85–88]. While endoscopic decompression may be definitive treatment for intravesical ureteroceles, partial nephrectomy appears to be more definitive for extravesical ureteroceles. Other groups advocate primary endoscopic puncture even for patients with ectopic and duplex ureteroceles, because a third of patients are definitively treated and early decompression is presumed to reduce the risk of pyelonephritis [87].

Incontinence may be seen after the initial treatment of ectopic ureteroceles and was thought to be related to iatrogenic bladder neck or external urinary sphincter injury at surgery. However, Husmann et al. observed that, in patients treated with partial nephrectomy alone, 10% subsequently developed urinary stress incontinence, despite the absence of any bladder neck surgery [89]. It seems that large ureteroceles are capable of significantly distorting the developing bladder neck and urethra, which will not become apparent until the system is decompressed. In a more recent study [90], the authors concluded that children with ectopic ureteroceles presenting with incontinence are at high risk for a high-capacity bladder with incomplete emptying and bladder dysfunction following bladder neck procedures. They concluded that this was not related to the operative intervention, but rather was an integral part of the underlying disorder.

Case: An 11-year-old continent girl presented with recurrent febrile urinary tract infections. Sonography revealed duplications of both kidneys and a large ectopic ureterocele draining the upper moiety of the right kidney. The VCUG demonstrated right-sided reflux into both moieties on the right side. An endoscopic examination revealed a ureterocele that extended into the bladder neck and upper one-third of the urethra. An endoscopic puncture and decompression of the ureterocele was performed. Postoperatively, the patient experienced moderate stress incontinence that she had not manifested preoperatively and a VCUG revealed persisting right high-grade reflux. A right-sided common sheath reimplant, ureterocele excision, and bladder neck reconstruction were performed. Five years later, she remains continent and free of infections off antibiotic prophylaxis.

This clinical evidence would suggest that once a large ectopic ureterocele is deflated, function of the bladder neck and urethra may be impaired due to distortion of these structures by the long-standing distention.

23 Physiology of Micturition

Shachi Tyagi, Pradeep Tyagi, Naoki Yoshimura, and Michael B. Chancellor

INTRODUCTION

Micturition describes a dynamic process that alternates between phases of storage and expulsion of urine stored in the urinary bladder. The storage phase typically extends for hours, whereas the expulsion phase lasts for a few seconds. Reciprocal contraction and relaxation of smooth muscle in the bladder and urethra is required for these two phases of different duration to happen, which is accomplished by the complex interactions among smooth muscle, connective tissue, urothelium, and supportive structures with innervation. The relay of afferent input from the bladder to the neural circuitry in the brainstem, in particular the periaqueductal gray (PAG) and the pontine micturition center (PMC), switches on the periodic transformation of the lower urinary tract from the mode of bladder filling to voiding [1–3] (Figure 23.1). The volitional control over this dynamic process is lacking in infants, but is gained through learning by the age of 5 in most individuals. The micturition in both sexes is influenced by neural, biomechanical, biochemical, and morphologic properties of the bladder and urethra, as well as the hormonal influences and unique pelvic and perineal anatomy [4].

Role of Bladder Anatomy in Micturition Reflex

The muscular and membranous structure of bladder is well suited for the storage phase of micturition that can last up to several hours in healthy individuals. The storage function of bladder is therefore dependent on the stretching of a compliant bladder wall, which allows it to store a socially adequate volume of urine without significant rise in bladder wall tension. Bladder emptying requires a synchronous activation of all the smooth muscles. Uneven spread of contraction across bladder wall may cause stretching of contracted regions and prevent the rise in pressure necessary for urine to be expelled through the urethra.

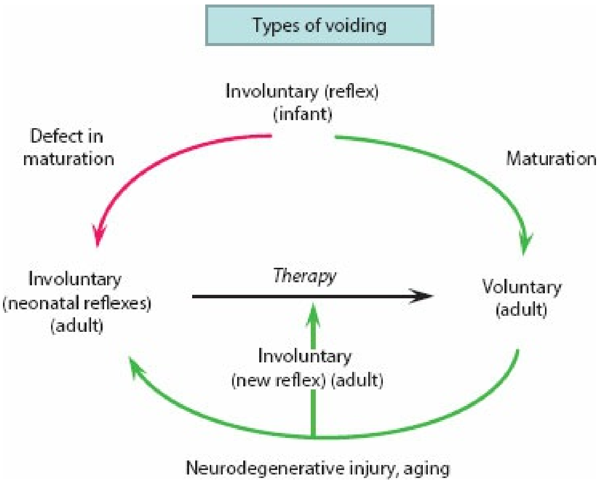
Histological examination of the bladder body reveals that bladder wall is an interlacing bundle of disorganized smooth muscle, where myofibrils are arranged into fascicles in random directions [5]. This architecture differs from the discrete circular and longitudinal smooth muscle layers in the ureter or gastrointestinal tract. The bladder outlet is composed of the bladder base, urethra, and external urethral sphincter (EUS). The bladder base has a laminar architecture with a superficial longitudinal layer lying beneath the trigone. A muscle layer deep to the superficial layer is continuous with the detrusor [6–8] and the smaller muscle bundles in the bladder base exhibit a predominantly circular orientation.

Detrusor smooth muscles have a broad length–tension relationship, which allows tension to be developed over a large range of resting muscle lengths [9]. Elastic characteristics of bladder wall play a role in the development of bladder wall tension [10]. Although spontaneous mechanical activity is noted in isolated detrusor strips of small mammals [11] and humans, the fused tetanic contractions typically seen in smooth muscles from the gastrointestinal tract and uterus are almost never seen in the normal bladder. The lack of tetanic contractions suggests that electrical coupling of detrusor smooth muscle cells [12] is absent.

Furthermore, tissue impedance measurement also supports the relatively poor electrical coupling of detrusor smooth muscles compared to other smooth muscles [13,14]. Poor electrical coupling may assist in the prevention of synchronous activation of the smooth muscle cells during bladder filling. Nevertheless, the existence of some degree of coupling within a muscle bundle cannot be ruled out as the length constant of a bundle can be easily measured [13,14]. Studies on postnatal development of the rat bladder have shown that electrical couplings between detrusor cells seem to be higher in neonates compared to adults because coordinated, large-amplitude, low-frequency contractile activity seen in the neonates declines and is replaced by low-amplitude, high-frequency, more irregular activity in older rats, which appears to depend on the disruption of the intercellular smooth muscle communication [15].

Instead of electrical coupling, there has been evidence reported of gap junction coupling between detrusor smooth muscle cells of the human and guinea pig bladder from whole-cell patch-clamp recordings [16] and Ca^2 imaging [17]. In addition, the significant expression of connexin 43 and 45 gap junction proteins has been reported in human detrusor muscles (Figure 23.2) [16,18]. Gap junction connexin proteins oligomerize into hexameric assemblies called connexons, which dock head to head with partner connexons positioned on neighboring cells to provide channels for paracrine messengers [19]. Recent studies on mouse bladder suggest that the circadian oscillation of Cx43 contributes to increased bladder capacity during day seen in rodents [20]. It is surmised that the uninhibited detrusor contractions occurring in the overactive and aging bladders may be due to reversal in the properties of the cell coupling [21–25] from gap junction [26] back to the electrical as seen in neonates.

Another important subcellular structure important for detrusor signaling is the caveolae, which are specialized regions of the cell membrane that modulate signal transduction, by clustering muscarinic and purinergic receptors within the sarcolemma. Postnatal development of bladder in rats is associated with increase in caveolin protein expression [27]. In contrast, decreased density of caveolin-2 and caveolin-3 protein expression was noted in rat detrusor smooth cells from 12-month-old rats relative to 12-week-old rats [28]. Age-dependent changes in caveolar morphology also revealed the reversal of infantile expression of caveolin protein at old age. Estrogens are known to promote the survival of smooth muscle cells and neurons by increase in caveolae [27], whereas depletion of estrogen is known to decrease the caveolae.



Types of voiding
Involuntary (reflex) (infant)
Defect in maturation
Maturation
Involuntary (neonatal reflexes) (adult)
Therapy
Voluntary (adult)
Involuntary (new reflex) (adult)
Neurodegenerative injury, aging

Figure 23.1 Bladder's "circle of life" by influence of maturation, pathologic processes, and aging. In infants, voiding is initiated and coordinated by reflex circuits. After maturation of central neural pathways, voiding is controlled voluntarily by neural circuitry in higher centers in the brain. A defect in neural maturation allows involuntary voiding to persist in adults. Aging, neural injury, or diseases such as benign prostatic hyperplasia can disrupt the central voluntary micturition neural pathways. Pathologic processes can lead to the formation of new reflex circuitry by reemergence of primitive reflex mechanisms that were present in the infant or that appear as the result of synaptic remodeling. The goal of therapy is to reverse the pathologic process and to reestablish normal voluntary control of voiding.

Role of Urothelium

The superficial cell layer of bladder known as urothelium was traditionally considered to play the role of blood–bladder barrier, which blocks the ingress of toxic constituents from stored urine and thereby prevents uremia. Urothelium has to expand in size during filling phase when detrusor smooth muscles are relaxing and expanding the size of the bladder. Expansion of urothelium while maintaining barrier function protects the smooth muscle and intrinsic nerves from urine exposure [29]. Recent investigations have revealed that urothelium conveys the stimulus of bladder distension, which initiates activity in low-threshold mechanoreceptive afferents during storage and also conveys the magnitude of detrusor contractions during voiding. Urothelium is considered to act as a lumenal sensor–transducer and communicate directly with the suburothelial afferent nerves by releasing various autocrine and paracrine factors [30].

Autonomous detrusor activity detected during storage is known to facilitate the generation of bladder sensation and afferent activity. Although the source of autonomous detrusor activity is unclear, spontaneous contractile activity of detrusor myocytes was suspected to trigger spontaneous contractions through gap junctions [31]. Alternatively, another population of cells located in various sites the bladder known as interstitial cells have been proposed for the pacemaking role in spontaneous activity of the bladder [32,33]. Interstitial cells have been identified in human and guinea pig ureter, urethra, and bladder body [33–35]. Urothelium is believed to secrete paracrine factors that seem to reduce the spontaneous activity of detrusor [30] because the frequency of whole-cell Ca^2 flashes of detrusor smooth muscle cells was higher in preparations with intact urothelium relative to those with denuded urothelium.

Suburothelial Interstitial Cells

Distension of bladder during filling of urine stretches the urothelium and causes the nonneuronal release of acetylcholine (ACh) or adenosine triphosphate (ATP) from pannexin-1 hemichannels [36]. ATP exerts a prominent role on afferent arm of micturition reflex as it initiates the voiding reflex *via* the activation of $P2X_3$ receptors on suburothelial sensory nerve fibers [35]. The stretch-evoked ATP release is increased in diseased condition such as chronic spinal cord injury [37,38]. The ATP release from stretched urothelium is reported to be further augmented in aging and in obstructed bladder [39–43], which may be related to increased voiding frequency and enhanced low-threshold afferent nerve activity noted in these conditions. Elevated expression of $P2X_3$ receptor in urothelium and interstitial cells has been reported in association with aging [40] and in rat model of bladder obstruction [44]. ATP is also a cotransmitter of ACh in the parasympathetic nerves and participates in both afferent and efferent transmissions of micturition reflex [45].

Suburothelial (or lamina propria) interstitial cells in the human bladder have also been termed myofibroblasts as they stain for vimentin and alpha-smooth muscle actin but not for desmin [46]. Immunohistochemical studies show the expression of P2Y receptors, most notably $P2Y_6$ receptors [22] and M_3 muscarinic receptors in the suburothelial interstitial cells from guinea pigs [21–25]. These cells are linked by gap junctions composed of connexin 43 proteins, which make close appositions with C-fiber nerve endings in the suburothelium to suggest that there is a network of functionally connected interstitial cells immediately below the urothelium that can be modulated by other nerve fibers [22] (Figure 23.2).

Isolated suburothelial interstitial cells respond to application of ATP by inducing inward currents associated with elevated intracellular Ca^2 [35]. Because ATP or ACh is known to be released from the urothelium during bladder stretch, suburothelial interstitial cells that respond to ATP via P2Y receptor activation [21–25] are in an ideal position between the urothelium and nerve endings to modify a sensory feedback mechanism [21–25]. In the human bladder, increased expression of muscarinic M_2 and M_3 receptors in suburothelial interstitial cells is found and correlated with urgency score in humans with idiopathic detrusor overactivity [47].

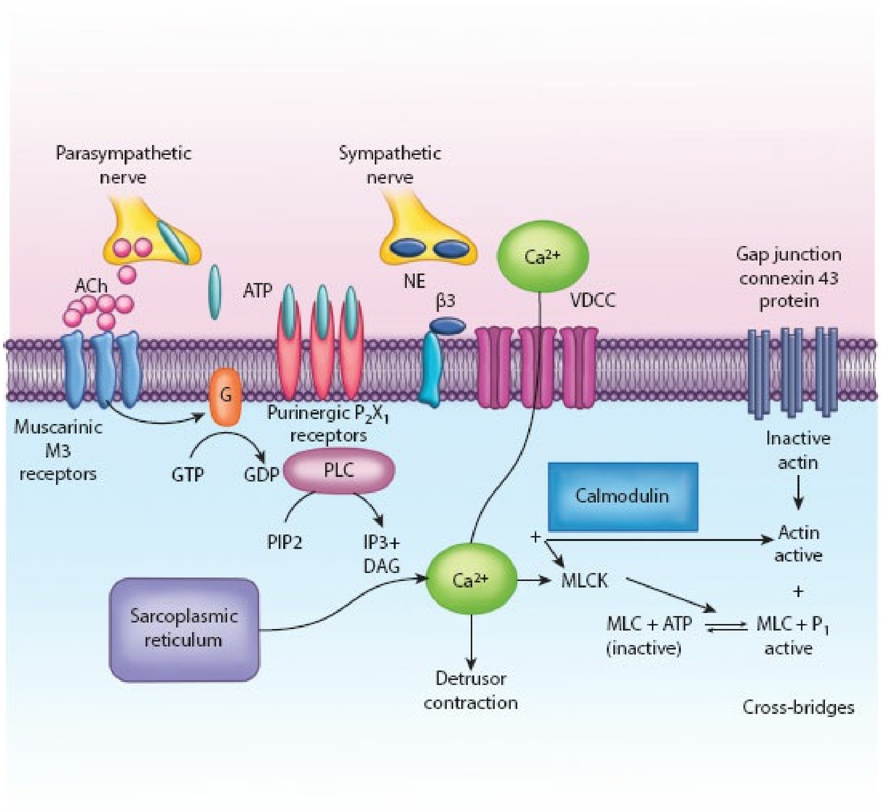


Figure 23.2 Biochemistry of detrusor contraction: Detrusor contraction during voiding is mediated by action of acetylcholine (ACh) released from the parasympathetic nerves together with adenosine triphosphate (ATP) at the detrusor neuromuscular synapse. ATP exerts mutually exclusive effects through the activation of excitatory purinergic $P2X_1$ receptors on the detrusor smooth muscle, and action on inhibitory $P2Y_1$ receptors controls ACh release from cholinergic nerve endings. The relaxation of detrusor required for storage phase is mediated by the action of norepinephrine (NE) released by the sympathetic nerves acting on β_3-receptors expressed in detrusor. Activation of afferents residing in the suburothelial layer during storage phase is maintained by ACh and ATP released by stretched urothelium. Afferent and efferent communication in the bladder is facilitated by gap junction proteins.

Intradetrusor Interstitial Cells

Interstitial cells are also found in the detrusor layer and shown to be spontaneously active [33]. These cells stain for c-Kit and are located along both boundaries of muscle bundles in the guinea pig bladder [34,48,49]. They can increase Ca^2 activity in response to cholinergic stimulation via M3 muscarinic receptor activation and can be spontaneously active. This suggests they could act as pacemakers or intermediaries in transmission of nerve signals to smooth muscle cells [48,50,51]. Hashitani and colleagues [49] suggested that interstitial cells in the detrusor may be more important for modulating the transmission of Ca^2 transients originating from smooth muscle cells rather than being the pacemaker of spontaneous activity because Ca^2 transients occur independently in smooth muscles and interstitial cells [34,49,52,53].

Potential Role of Phosphodiesterases and Prostaglandins

Interstitial cells throughout the bladder demonstrate immunoreactivity for cyclic nucleotide cyclic guanosine monophosphate (cGMP) [54,55]. The functional role of cGMP-dependent signaling was suggested by the attenuated increase in intracellular Ca^2 and current responses to ATP in guinea pig interstitial cells following the addition of sodium nitroprusside [56]. Thus, increased levels of cGMP in interstitial cells following inhibition of phosphodiesterase 5 may diminish the synchronicity between detrusor muscle bundles [34]. These cells are also a source of prostaglandin E_2 (PGE_2) because of their expression of cyclooxygenase, which is known to induce spontaneous activity independent of efferent nerve activity [57,58]. Expression of EP1 receptor in urothelium has recently been reported [42], which could be activated by PGE2 to release ATP and increase detrusor contractility. Reduced spontaneous activity of rabbit bladder muscle strips after exposure with PGE_2 receptor antagonists is consistent with the stated role of EPI receptor and its ligand [59] (Figure 23.2).

NEUROPHYSIOLOGY

Urine Storage

The bladder pressure remains low during storage or bladder filling phase till the bladder volume remains lower than the threshold for inducing voiding. Denny-Brown and Robertson showed that under normal conditions (i.e., in the absence of prior bladder distension) the rise in intravesical pressure is linear with rise in bladder volume until high volumes were reached [60]. The accommodation of the bladder to increasing volumes of urine is primarily a passive phenomenon dependent on the viscoelastic characteristics of bladder wall and the quiescence of the parasympathetic efferent pathway [61–63].

Bladder distension–induced afferent activity triggers spinal reflex pathways, which facilitate storage by directly enhancing thoracolumbar sympathetic outflow and somatomotor discharge [64]. Reflex activation of the sympathetic outflow inhibits any neurally mediated contractions of the bladder during filling phase of micturition [63,65,66]. Organization of this reflex response in the lumbosacral spinal cord is confirmed by its persistence even after transection of the spinal cord at the thoracic levels (Figure 23.3). However, this bladder to sympathetic mechanism to suppress detrusor contractions during urine storage may be weak in humans, given that bilateral retroperitoneal lymph node dissection (involves destruction of sympathetic chains) has no discernible alteration of filling or storage function in humans.

During filling, sympathetic and somatic spinal reflexes are responsible for the low intravesical pressure and high urethral pressure maintained by the tonic activity of smooth and striated urethral sphincters, respectively [65] (Figure 23.3). The rise in intra-abdominal pressure during filling is also resisted by sympathetic and somatic spinal reflexes. The increased efferent firing in the pudendal nerve and the higher outlet resistance during filling are responsible for the maintenance of urinary continence and the increased activity of sphincter electromyogram during storage (Figure 23.4).

The bladder afferent input during bladder filling activates pudendal motoneurons as a result of somatic spinal reflex (the guarding reflex) [67], whereas the motoneurons are reciprocally inhibited during voiding [1]. EUS motoneurons are also activated by urethral or perineal afferents in the pudendal nerve [68]. This reflex may represent, in part, a continence mechanism that is activated by proprioceptive afferent input from the urethra or pelvic floor to induce closure of the urethral outlet. These excitatory sphincter reflexes are organized in the spinal cord.

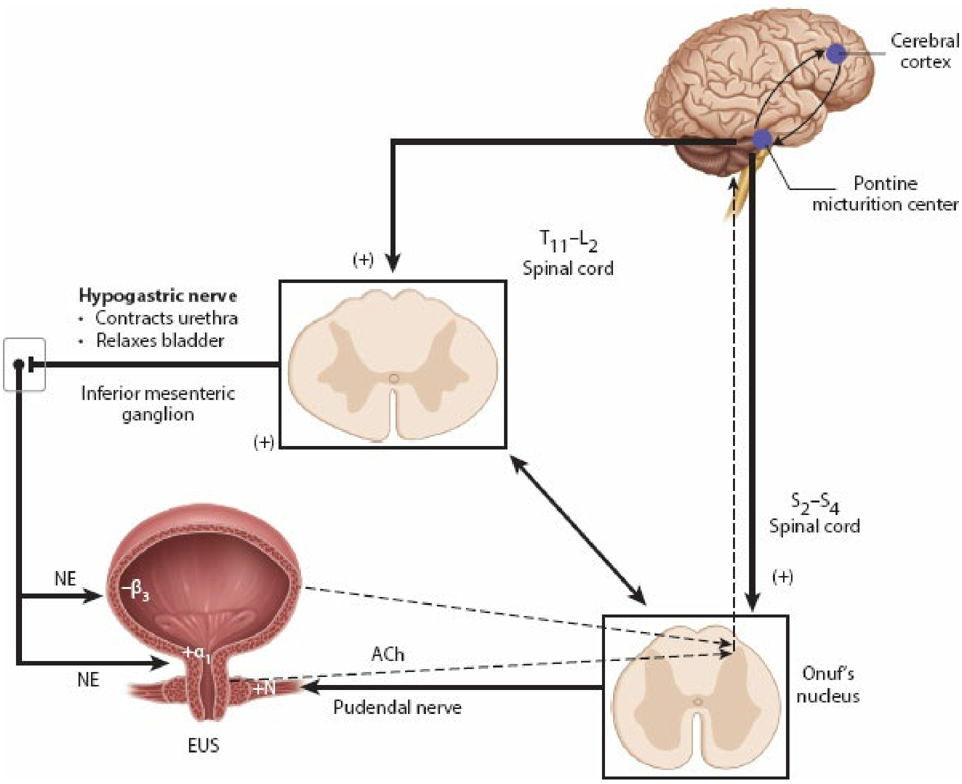

Figure 23.3 Storage reflexes. During the storage of urine, the distention of the bladder produces low-level bladder afferent firing. Afferent firing in turn stimulates the sympathetic outflow to the bladder outlet (base and urethra) and pudendal outflow to the external urethral sphincter (EUS). These responses occur by spinal reflex pathways and represent "guarding reflexes," which promote continence. Sympathetic firing also inhibits detrusor muscle and transmission in intramural ganglia. Afferent input (*dashed lines*) from the urethra and EUS can inhibit parasympathetic outflow to the detrusor through a spinal reflex circuit. ACh, acetylcholine; NE norepinephrine; excitatory (+) and inhibitory (−) mechanisms.

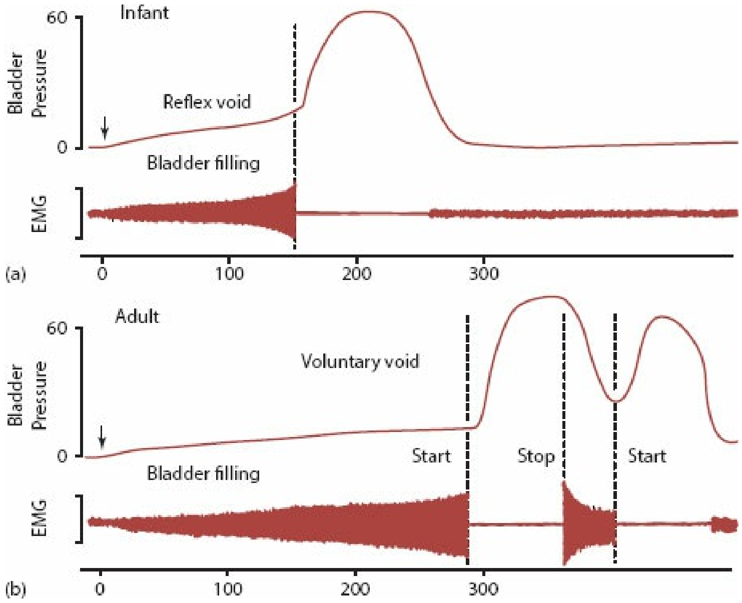

Figure 23.4 Combined cystometrogram and sphincter electromyogram (EMG) comparing reflex voiding responses in an infant (a) and a voluntary voiding response in an adult (b). The x-axis in all records represents bladder volume in milliliters, and the y-axis represents bladder pressure in centimeters of water and electrical activity of the electromyographic recording. On the left side of each trace, the arrows indicate the start of a slow infusion of fluid into the bladder (bladder filling). Vertical dashed lines indicate the start of sphincter

relaxation that precedes by a few seconds the bladder contraction in (a) and (b). In (b), note that a voluntary cessation of voiding (stop) is associated with an initial increase in sphincter electromyographic activity followed by a reciprocal relaxation of the bladder. A resumption of voiding is again associated with sphincter relaxation and a delayed increase in bladder pressure. (From de Groat WC, Basic neurophysiology and neuropharmacology, in P Abrams, S Khoury, and A Wein, eds., *Incontinence*, Health Publications, Plymouth, U.K., 1999, p. 112. With permission.)

Bladder Emptying

Bladder emptying requires sudden complete relaxation of striated sphincter followed immediately by increased intravesical pressure. The transition from storage phase to voiding phase can occur either involuntarily (reflexively) or voluntarily. The former is readily demonstrated in the human infant or in patients with neuropathic bladder when the bladder wall tension exceeds the micturition threshold due to increased urine volume. Voiding is initiated upon cessation of sympathetic and somatic input to the detrusor and sphincter, which causes sphincters to relax and the bladder neck to assume the shape of a funnel, and the concomitant increased parasympathetic activity causes the detrusor contraction to generate pressure for overcoming resistance generated by the collapsed urethra.

At this point, increased afferent firing from tension receptors in the bladder reverses the pattern of efferent outflow, producing firing in the sacral parasympathetic pathways and inhibition of sympathetic and somatic pathways. Reversal in efferent outflow in both sympathetic and somatic innervations to the urethra and sphincter causes a reflex relaxation followed in a few seconds by parasympathetic nerve–mediated detrusor contraction (Figure 23.5). As a result, the pressure inside bladder rises and the urethral pressure falls, which is a prerequisite for the urine expulsion.

ACh released from the parasympathetic nerves together with ATP [45] at the detrusor neuromuscular synapse mediates detrusor contraction. ATP exerts mutually exclusive effects through the activation of excitatory purinergic $P2X_1$ receptors on the detrusor smooth muscle, and action on inhibitory $P2Y_1$ receptors controls ACh release from cholinergic nerve endings [44]. Elimination of urine is also facilitated by noncholinergic/nonadrenergic nitric oxide release onto the internal urethral sphincter, resulting in a relaxation of the urethral outlet [69,70] and by removal of excitatory inputs to the urethra.

Secondary reflexes elicited by flow of urine through the urethra also facilitate bladder emptying [61,66,71]. These reflexes require the integrative action of neuronal populations at various levels of the neuraxis (Figure 23.6). The parasympathetic outflow to the detrusor and urethra has a more complicated central organization involving spinal and spinobulbospinal pathways passing through a micturition center in the PMC (pons) (Fib. 6B). Complete bladder emptying is facilitated by urethra to bladder reflex occurring while urine is flowing through urethra as demonstrated in anesthetized cat experiments by Barrington [72,73] (Figure 23.5). Barrington identified two components of this reflex. One component was activated by a somatic afferent pathway in the pudendal nerve, which facilitated voiding via the supraspinal pathway involving the PMC [73] (Figure 23.6). The other component was activated by a visceral afferent pathway in the pelvic nerve to facilitate voiding at the spinal micturition center [72]. Studies [71] in the anesthetized rat have further confirmed the seminal findings of Barrington [74].

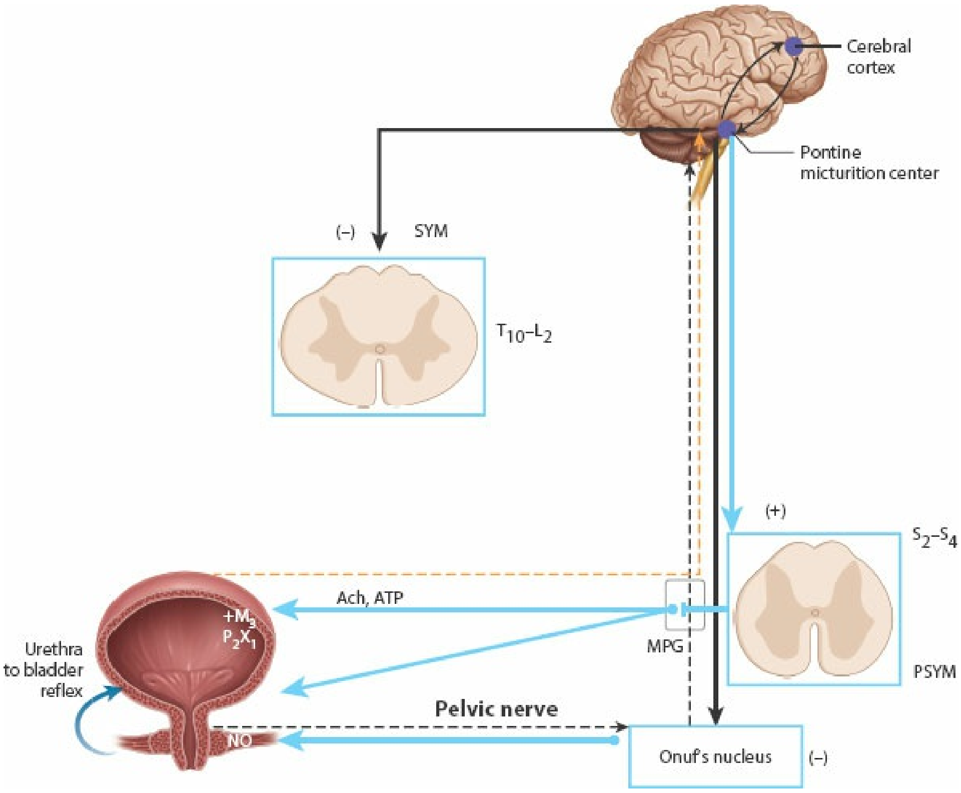

Figure 23.5 Voiding reflexes. At the initiation of micturition, intense vesical afferent activity activates the brainstem micturition center, which inhibits the spinal guarding reflexes (sympathetic and pudendal outflow to the urethra). The pontine micturition center (PMC) also stimulates the parasympathetic outflow to the bladder and internal sphincter smooth muscle. Maintenance of the voiding reflex is through ascending afferent input from the spinal cord, which may pass through the periaqueductal gray (PAG) matter before reaching the PMC. Afferent pathway (*colored dashed line*) from the detrusor activates spinal reflex mechanisms that induce firing in the somatic cholinergic nerves to the external urethral sphincter (EUS), sympathetic adrenergic nerves to the urethral smooth muscle, and cholinergic and nitrergic nerves to the urethral smooth muscle. Bulbospinal pathways from the brain can modulate these spinal reflex mechanisms. Urethral afferents (*black dashed line*) activated by urine flowing through urethra can further facilitate parasympathetic efferent outflow to the detrusor to complete voiding by means of a supraspinal pathway passing through the PMC as well as a spinal reflex pathway. ACh, acetylcholine; NEPI, norepinephrine; NO, nitric oxide; excitatory (+) and inhibitory (−) mechanisms.

Measurements of reflex bladder contractions under isovolumetric conditions during continuous urethral perfusion (0.075 mL/min) revealed that the frequency of micturition reflexes was significantly reduced when urethral perfusion was stopped or after urethral infusion of lidocaine (1%). Desensitization of the urethral afferent with intraurethral capsaicin also dramatically altered the micturition reflex. Intraurethral infusion of nitric oxide donors (S-nitroso-N-acetylpenicillamine [SNAP] or nitroprusside, 1–2 mM) markedly decreased the urethral perfusion pressure (approximately 30%) and decreased the frequency of reflex bladder contractions (45%–75%) but did not change the amplitude of bladder contractions.

The existence of this pudendal nerve–mediated reflex has been confirmed as low-frequency electrical stimulation of afferent axons in the human pudendal nerve and the deep perineal nerve, a caudal branch of the pudendal nerve in cats that can initiate reflex bladder contractions and voiding [75,76]. The existence of urethra to bladder reflex may explain why stress incontinence and urge incontinence are comorbidities in women. Women with mixed incontinence may have detrusor overactivity activated by leakage of urine into the urethra due to stress incontinence, which support the theory of stress incontinence inducing urge incontinence [77]. Interestingly, surgical cure of the stress incontinence of women with mixed incontinence has resolved the urge incontinence in up to half of the patients.

Micturition Control Circuitry

Volitional control over micturition is maintained by multiple reflex pathways organized in the brain and spinal cord to mediate the coordination between the urinary bladder and the urethra. Inputs from supraspinal, spinal, and peripheral nervous system are necessary to maintain "switch-like" patterns of filling and voiding activity (Figures 23.4 and 23.5), which maintain a reciprocal relationship between the urinary bladder and the urethral outlet [78,79]. The principal reflex components of these switching circuits are listed in Figures 23.4 and 23.6. Some reflexes promote urine storage, whereas others facilitate voiding. During the filling phase, there is an inhibitory discharge to PMC for relaxing the bladder and tightening the sphincter (guarding reflex).

Figure 23.6 Schematic of micturition control circuitry: Sympathetic preganglionic pathways emerge from the lumbar spinal cord and pass to the sympathetic chain ganglia (SCG) and then through the inferior splanchnic nerves (ISNs) to the inferior mesenteric ganglia (IMG). Preganglionic and postganglionic sympathetic axons then travel in the hypogastric nerve (HGN) to the pelvic plexus and the urogenital organs. Parasympathetic preganglionic axons that originate in the sacral spinal cord pass in the pelvic nerve to ganglion cells in the pelvic plexus and to distal ganglia in the organs. Sacral somatic pathways are contained in the pudendal nerve, which provides an innervation to the external urethral sphincter (EUS) muscles. The pudendal and pelvic nerves also receive postganglionic axons from the caudal sympathetic chain ganglia. These three sets of nerves contain afferent axons from the lumbosacral dorsal root ganglia (DRG).

It is also possible that individual reflexes might be linked together in a serial manner to create complex feedback mechanisms. For example, the bladder to EUS guarding reflex that triggers sphincter contractions during bladder filling could, in turn, activate sphincter muscle afferents that initiate an inhibition of the parasympathetic excitatory pathway to the bladder. Thus, a bladder to sphincter to bladder reflex pathway could in theory contribute to the suppression of bladder activity during urine storage. Alterations in these primitive reflex mechanisms may contribute to neurogenic bladder dysfunction.

Afferent Pathways

An intact afferent system is crucial to physiological voiding and bladder filling. During the filling phase, mechanoreceptors in bladder wall initiate visceral afferent (Aδ-fibers) activity that is carried by afferent axons in the pelvic nerve that synapse on spinal interneurons in lumbosacral spinal cord [62,80,81]. The pelvic nerve afferents consist of myelinated (A) and unmyelinated (C) axons to monitor the volume of the bladder and the amplitude of the bladder contraction (Figure 23.5). The primary afferent neurons of the pelvic and pudendal nerves are contained in sacral dorsal root ganglia (DRG), whereas afferent innervation in the hypogastric nerves arises in the rostral lumbar DRG. The central axons of the DRG neurons carry the sensory information from the lower urinary tract to second-order neurons in the spinal cord [80,82–84] (Figure 23.6). Visceral afferent fibers of the pelvic [82] and pudendal [83] nerves enter the cord and travel rostrocaudally within Lissauer's tract.

During neuropathic conditions and possibly inflammatory conditions, there is recruitment of C fibers from a new functional afferent pathway that can cause urge incontinence and possibly bladder pain. The suppression of detrusor overactivity in patients by sacral root stimulation may reflect in part the activation of the afferent limb of these visceral-bladder and somatic-bladder inhibitory reflexes [85–89].

Spinal and Supraspinal Pathways Involved in the Micturition Reflex

In the spinal cord, afferent pathways terminate on second-order interneurons that relay information to the brain or to other regions of the spinal cord including the preganglionic sympathetic fibers from the intermediolateral cell column of the lower thoracic (T10) to upper lumbar (L2) spinal cord that form the thoracic and lumbar splanchnic nerves. The preganglionic fibers then synapse on the prevertebral inferior mesenteric ganglia (IMG) or paravertebral ganglia and travel along the hypogastric and pelvic nerves, respectively. Because polysynaptic pathways but not monosynaptic pathways mediate bladder, urethral, and sphincter reflex, interneuronal mechanisms play an essential role in the regulation of lower urinary tract function. Electrophysiological [90,91] and neuroanatomic [79,92–94] techniques have identified lower urinary tract interneurons in the same regions of the cord that receive afferent input from the bladder.

Pharmacological experiments revealed that glutamic acid is the excitatory transmitter in these pathways [84]. The inhibitory neurons release γ-aminobutyric acid (GABA) and glycine. Reflex pathways that control the external sphincter muscles also use glutamatergic excitatory and GABAergic and glycinergic inhibitory interneuronal mechanisms. Stimulation of afferent fibers from various regions (anus, colon–rectum, vagina, uterine cervix, penis, perineum, pudendal nerve) can inhibit the firing of sacral interneurons evoked by bladder distention [90]. This inhibition may be a result of presynaptic inhibition at primary afferent terminals or be due to direct postsynaptic inhibition of the second-order neurons. Direct postsynaptic inhibition of bladder preganglionic neurons can also be elicited by stimulation of somatic afferent axons in the pudendal nerve or visceral afferents from the distal bowel [95,96].

Peripheral Nervous System

The lower urinary tract is innervated by three sets of the peripheral nerves involving the parasympathetic, sympathetic, and somatic nervous systems (Figure 23.6). Pelvic parasympathetic nerves arise at the sacral level of the spinal cord, excite the bladder, and relax the urethra. Lumbar sympathetic nerves inhibit the bladder body and excite the bladder base and urethra. Pudendal nerves excite the EUS. These nerves contain afferent (sensory) and efferent axons [62,63,94,97].

Parasympathetic Pathways

The preganglionic parasympathetic fibers arise from the ventral roots in the lateral part of the sacral intermediate gray matter in a region termed the sacral parasympathetic nucleus (S2–S4) and spinal cord to form the pelvic splanchnic nerves [63,82,84,98,99]. Upon coursing through and exiting the hypogastric and pelvic plexus, the fibers join the pelvic and pudendal nerves to synapse on terminal ganglia [1] and innervate the detrusor smooth muscle and urethra. The parasympathetic postganglionic neurons in humans are located not only in the detrusor wall layer but also in the pelvic plexus. This dual location can allow the possibility of afferent and efferent neuron interconnection at the level of the intramural ganglia in cauda equina or pelvic plexus injury [66,84]. Such injury leaves patients neurologically decentralized but may not be completely denervated.

Sympathetic Pathways

Sympathetic outflow from the rostral lumbar spinal cord provides a noradrenergic excitatory and inhibitory input to the bladder and urethra [69]. The peripheral sympathetic pathways follow a complex route that passes through the sympathetic chain ganglia (SCG) to the IMG and then through the hypogastric nerves to the pelvic ganglia [100]. The activation of the sympathetic nerves induces relaxation of the bladder body and contraction of the bladder outlet and urethra, which contribute to filling phase in the bladder. Urine storage is facilitated by bladder wall relaxation and accommodation promoted by action of noradrenaline at β-adrenergic receptors in bladder [101] and activation of α-adrenergic receptors on the internal urethral sphincter resulting in contraction of the urethral outlet.

Somatic Pathways

The EUS motoneurons are located along the lateral border of the ventral horn of the sacral (S2–S4) spinal cord, commonly referred to as Onuf's nucleus [83]. Sphincter motoneurons also exhibit transversely oriented dendritic bundles that project laterally in the lateral funiculus, dorsally into the intermediate gray matter, and dorsomedially toward the central canal. Spinal reflex pathways not only enhance sympathetic outflow but also α-motoneuron discharge from Onuf's nucleus. Propagation of this signal along the pudendal nerve to the EUS elicits skeletal muscle contraction by activating nicotinic ACh receptors to provide voluntary control over urinary continence.

The inhibition can be induced by activation of afferent input from visceral organs including the penis, vagina, rectum, perineum, urethral sphincter, and anal sphincter [63,102,103]. Contractions of the EUS and possibly other pelvic floor striated muscles can stimulate firing in muscle proprioceptive afferents, which then activate central inhibitory mechanisms to suppress the micturition reflex (Figure 23.5). Electrical stimulation of somatic afferent pathways projecting in the pudendal nerve to the caudal lumbosacral spinal cord can also inhibit voiding function.

Electrophysiological studies in cats showed that the inhibition was mediated by suppression of interneuronal pathways in the sacral spinal cord and also by direct inhibitory input to the parasympathetic preganglionic neurons [104]. A similar inhibitory mechanism has been identified in monkeys by direct stimulation of the anal sphincter muscle [105]. The inhibition of EUS reflex activity during micturition is dependent, in part, on supraspinal mechanisms because it is weak or absent in chronic spinal animals and humans, resulting in simultaneous contractions of bladder and sphincter (i.e., detrusor sphincter dyssynergia) [106,107]. In the adult, the reflex loop passes through the pontine center.

Pontine Micturition Center and Brainstem Modulatory Mechanisms

Various studies indicate that the micturition reflex is normally mediated by a spinobulbospinal reflex pathway passing through relay centers in the brain [61,62,66,78]. The occurrence of voiding dysfunction following lower thoracic spinal cord injury highlights the crucial role of supraspinal circuitry in voiding relative to the filling phase. The experiments involving brain-lesioning techniques in animals have confirmed that neurons in the brainstem at the level of the inferior colliculus have an essential role in the control of the parasympathetic component of micturition [61,62,66,108].

Removal of brain areas above the colliculus by intercollicular decerebration usually facilitates micturition by elimination of inhibitory inputs from more rostral centers. However, transections at any point below the colliculi abolish micturition. In addition to providing axonal inputs to the locus coeruleus and the sacral spinal cord [109–111], neurons in the dorsolateral pontine tegmentum termed pontine micturition center (PMC) also send axon collaterals to the paraventricular thalamic nucleus, which is thought to be involved in the limbic system modulation of visceral behavior [110]. Some neurons in the PMC also project to the PAG region [112], which regulates many visceral activities as well as pain pathways [113]. Thus, neurons in the PMC communicate with multiple supraspinal neuronal populations that may coordinate micturition with other functions of the organism.

Although the circuitry in humans is uncertain, brain imaging studies have revealed increases in blood flow in this region of the pons during micturition [114]. This change presumably reflects increases in neuronal activity. Thus, the PMC appears critical for micturition across species. In the midbrain, recent evidence supports that mesencephalic PAG can directly receive information of bladder fullness bypassing the local spinal reflexes via ascending spinal tract neurons. After cortical processing, the

PAG sends excitatory input to PMC, which has descending cortical projections that synapse on preganglionic parasympathetic neurons and inhibitory interneurons in the sacral spinal cord to prevent excitatory input reaching the urethral sphincters. Efferent parasympathetic outflow is enhanced by PMC and the preganglionic sympathetic and α-motoneuron discharge to the sphincter is attenuated during voiding. The ascending excitation to the dorsolateral metencephalon is diminished by the reduced bladder distension as a consequence of voiding, which switches on storage phase once again. PMC plays an important role in the integration of the micturition reflex [112].

Central Pathways That Modulate the Micturition Reflex

Transneuronal virus tracing methods have identified virus-infected cells in several regions of the hypothalamus and the cerebral cortex after injection of pseudorabies virus into the lower urinary tract in animals [92–94,115]. Neurons in the cortex were located primarily in the medial frontal cortex. Tracers injected into the paraventricular nucleus of the hypothalamus labeled terminals in the sacral parasympathetic nucleus as well as the sphincter motor nucleus [116]. The influence of the cortex on voiding function could be mediated by a number of pathways, including direct cortical projections from the prefrontal cortex (PFC) and insular cortex to the PMC or projections through the hypothalamus and the extrapyramidal system [1]. Studies in humans indicate that voluntary control of voiding is dependent on connections between the frontal cortex and the septal–preoptic region of the hypothalamus as well as on connections between the paracentral lobule and the brainstem. Lesions to these areas of cortex appear to directly increase bladder activity by removing cortical inhibitory control [1].

Human Brain Imaging Studies

Evidence from human imaging studies has supported findings from preclinical studies and demonstrated the active control of micturition by brain during filling and voiding [117]. Functional neuroimaging have been performed in normal volunteers using single-photon emission computed tomography, positron-emission tomography, functional magnetic resonance imaging, and near-infrared spectroscopy to observe activation in brain areas responsible for the perception of bladder fullness and the sensation of the desire to void during bladder filling, whereas others examined brain activity during micturition [118,119]. Brain is activated during bladder filling [120] particularly in the PAG, the midline pons, the anterior and the mid-cingulate gyrus, the anterior insula, and bilaterally the frontal lobes, supplementary motor area, referred to as the “frontal micturition center” [120,121] (Figure 23.7).

The constellation of these cortical areas seem to “switch on and off” the spino–bulbo–spinal micturition reflex. The results were consistent with the notion that the PAG receives information about bladder fullness and then relays this information to other brain areas involved in the control of bladder storage. In fMRI studies in men and women, activation during urinary storage is found in the supplementary motor area, mid-cingulate cortex, insula, and right PFC, and the right anterior insula and midbrain PAG were more active at higher rather than at lower bladder volumes [122,123].

PET scan studies in normal men and women revealed that during voiding, two cortical areas (the dorsolateral PFC and anterior cingulated gyrus) were active (i.e., exhibited increased blood flow). The hypothalamus including the preoptic area as well as the pons and the PAG also showed activity in concert with voluntary micturition [112,114,124]. Another PET study during voiding also confirmed that micturition was associated with increased activity in the pons, inferior frontal gyrus, hypothalamus, and PAG while also showing activity in several other cortical areas (postcentral gyrus, superior frontal gyrus, thalamus, insula, and globus pallidus) and the cerebellar vermis [125]. Neuroimaging fMRI studies also evaluated the effect of voluntary contractions of the pelvic floor during urine withholding or during cold stimulation on the activation of the parietal cortex, cerebellum, putamen, and supplementary motor area (SMA) [126] or the frontal cortex, basal ganglia, and cerebellum [127].

Figure 23.7 (a) Simplified model of supraspinal control over micturition. (b) Brain areas activated by storage and voiding involved in brainstem and spinal cord reflexes that act as "switch" (on-voiding; off-storage) identified by PET and fMRI. Brain areas activated during bladder filling are the PAG, the midline pons, the anterior and mid-cingulate gyrus, the anterior insula, and bilaterally the frontal lobes, supplementary motor area (SMA) referred to as the "frontal micturition center." Ascending afferent fibers (afferents) carry the information from the bladder synapse in the periaqueductal gray (PAG) and are relayed to the right insula (RI), forming the substrate for sensation. The anterior cingulate gyrus (ACG) is responsible for monitoring, arousal, and efferent output to the PAG and pontine micturition center (PMC). The prefrontal cortex (PFC) is involved in voluntary decision about voiding and generates efferent signals to control ACG and ultimately PMC. PMC then provides motor output to cause voiding. Impaired supraspinal control in cases of neurodegenerative disease leads to incontinence. (From Griffiths D and Tadic SD: Bladder control, urgency, and urge incontinence: Evidence from functional brain imaging. *Neurourol Urodyn*. 2008. 27(6). 466–474. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission.)

Based on the results, a simplified model of normal bladder filling is proposed, where the filling activates bladder and urethral afferents, which are received in the PAG, are mapped in the insula, and form the basis of the desire to void; the anterior cingulate gyrus (ACG) provides monitoring and control; the PFC makes voiding decisions. Voiding reflex is continuously inhibited at the PMC as the bladder fills until the decision to void is made in the PFC. The increasing desire to void corresponds to a gradual increase in insular response. Neuroimaging of patients with stroke, tumor, and multiple sclerosis has confirmed the role of these brain areas in micturition as the activated areas strikingly overlap the lesions described in patients.

Brain imaging studies have also been performed to identify changes in cerebral perception of detrusor overactivity. A PET study in patients with Parkinson's disease reported activation of the PAG, supplementary motor area, basal ganglia, and cerebellum during detrusor overactivity [128]. A fMRI study of subject with confirmed overactivity showed that infusion in the bladder is associated with activity in the PAG, thalamus, insula, and anterior cingulated gyrus; however, weak responses in the ACG at large bladder volumes are observed in urge-incontinent patients [129,130]. Cortical responses become exaggerated, especially in ACG. This may be both a learned reaction to previous incontinence episodes and a neural correlate of urgency [131]. Urge-incontinent subjects have weak responses or deactivation observed in the PFC or the limbic system, leading to a defect on supraspinal bladder control that may cause urge incontinence, and enhanced responses in the anterior cingulate gyrus, which may be due to abnormal bladder afferents or related to a loss of control in other brain areas and could be correlated with urge sensations [119]. Radiographic imaging of the CNS with control and dysregulation of the lower urinary tract is an exciting area of research, but the results are preliminary. Subjects are conscious and thinking about their bladder during the test and may have an indwelling catheter that may alter what parts of the brain are activated naturally or artificially.

CONCLUSIONS

Micturition is a function accomplished by unique biomechanics of bladder and urethral muscles as well as by a complex neural control system located in the brain and spinal cord. Storage of urine in the bladder till a socially acceptable moment arrives is mediated by increased sympathetic activity, which relaxes the urinary bladder via activation of postsynaptic β_3-receptors and contracts both urethral and prostatic smooth muscles via the α_1-adrenoceptor. The volitional control of micturition depends on an intact afferent system to relay the information on the state of bladder fullness to higher brain centers. Voiding in healthy adults happens after the PMC orders the sacral parasympathetic nucleus to increase parasympathetic activity, which activates postsynaptic muscarinic receptors to cause detrusor contraction and reciprocal relaxation of both urethral and prostatic smooth muscle by nitric oxide release. In addition, the rhabdosphincter is relaxed by inhibition of the pudendal nucleus at the sacral portion.

The neural control system performs like a switching circuit to maintain a reciprocal relationship between the reservoir (urinary bladder) and the outlet components (urethral sphincter) of the urinary tract. The switching circuit is modulated by various neurotransmitters and is sensitive to a variety of drugs. In infants, the switching circuits function in a purely reflex manner to produce involuntary voiding; however, in adults, urine storage and release are subject to volitional control. An understanding of the physiological events mediating micturition and continence provides a rational basis for the management of lower urinary tract dysfunction.

Pharmacology of the Bladder

Karl-Erik Andersson

INTRODUCTION

The lower urinary tract (LUT) is controlled by a complex interplay between the central (CNS) and peripheral nervous systems and local regulatory factors [1]. Malfunction at various levels may result in micturition disorders, which roughly can be classified as disturbances of storage or emptying. Failure to store urine may lead to various forms of incontinence (mainly urgency and stress incontinence), and failure to empty to urinary retention. Lower urinary tract symptoms (LUTS) include storage, voiding, and postmicturition symptoms. Storage symptoms (urgency, frequency with and without incontinence, nocturia) form the overactive bladder (OAB) syndrome, which may or may not be associated with involuntary detrusor contractions demonstrated by cystometry (detrusor overactivity [DO]). Pharmacological treatment of urinary incontinence (UI) is a main option, and several drugs with different modes and sites of action have been tried [2–4]. However, to be able to optimize existing therapies and to identify suitable new targets for treatment, knowledge about the mechanisms of micturition is necessary.

In the following texts, a brief review is given of the normal nervous control of the LUT and of some therapeutic principles used for treatment of UI.

NERVOUS MECHANISMS FOR BLADDER EMPTYING AND URINE STORAGE

The nervous mechanisms for bladder emptying and urine storage involve a complex pattern of afferent and efferent signaling in *parasympathetic*, *sympathetic*, and *somatic* nerves. These nerves constitute reflex pathways, which either maintain the bladder in a relaxed state, enabling urine storage at low intravesical pressure, or initiate micturition by relaxing the outflow region and contracting the bladder smooth muscle. Under normal conditions, there is a reciprocal relationship between the activity in the detrusor and the activity in the outlet region. During voiding, contraction of the detrusor muscle is preceded by a relaxation of the outlet region, thereby facilitating the bladder emptying [5–7]. On the contrary, during the storage phase, the detrusor muscle is relaxed, and the outlet region is contracted to maintain continence.

Contraction of the detrusor smooth muscle and relaxation of the outflow region result from activation of *parasympathetic* neurons located in the sacral parasympathetic nucleus in the sacral spinal cord at the level of S2–S4 [8]. The axons pass through the pelvic nerve and synapse with the postganglionic nerves either in the pelvic plexus, in ganglia on the surface of the bladder (vesical ganglia), or within the walls of the bladder and urethra (intramural ganglia) [9]. The preganglionic neurotransmission is predominantly mediated by acetylcholine acting on nicotinic receptors, although the transmission can be modulated by adrenergic, muscarinic, purinergic, and peptidergic presynaptic receptors [10]. The postganglionic neurons in the pelvic nerve mediate the excitatory input to the normal human detrusor smooth muscle by releasing acetylcholine acting on muscarinic receptors. However, an atropine-resistant (nonadrenergic, noncholinergic [NANC]) contractile component is regularly found in the bladders of most animal species [11,12]. Such a component can also be demonstrated in functionally and morphologically altered human bladder tissue [13–15] but contributes only to a few percent to normal detrusor contraction [1]. ATP is one important mediator of the NANC contraction [16,17] although the involvement of other transmitters cannot be ruled out [1,18]. The pelvic nerve also conveys parasympathetic nerves to the outflow region and the urethra. These nerves exert an inhibitory effect on the smooth muscle by releasing nitric oxide [19] and other transmitters [20–22].

Most of the *sympathetic* innervation of the bladder and urethra originates from the intermediolateral nuclei in the thoracolumbar region (T10-L2) of the spinal cord. The axons leave the spinal cord via the splanchnic nerves and either travel through the inferior mesenteric ganglia (IMF) and the hypogastric nerve or pass through the paravertebral chain to the lumbosacral sympathetic chain ganglia and enter the pelvic nerve. Thus, sympathetic signals are conveyed in both the hypogastric nerve and the pelvic nerve [9]. The preganglionic sympathetic transmission is, like the parasympathetic preganglionic transmission, predominantly mediated by acetylcholine acting on nicotinic receptors. Some preganglionic terminals synapse with the postganglionic cells in the paravertebral ganglia or in the IMF, while others synapse closer to the pelvic organs, and short postganglionic neurons innervate the target organs. Thus, the hypogastric and pelvic nerves contain both pre- and postganglionic fibers [9]. The predominant effect of the sympathetic innervation is to contract the bladder base and the urethra. In addition, the sympathetic innervation inhibits the parasympathetic pathways at spinal and ganglionic levels. In humans, noradrenaline is released in response to electrical stimulation in vitro [23], and the normal response to released noradrenaline is relaxation [24,25]. However, the importance of the sympathetic innervation for relaxation of the human detrusor has never been established. In contrast, in several animal species, the adrenergic innervation has been demonstrated to mediate relaxation of the detrusor during filling.

Most of the *sensory* nerves to the bladder and urethra originate in the dorsal root ganglia at the lumbosacral level of the spinal cord and travel via the pelvic nerve to the periphery. In addition, some afferents originate in the dorsal root ganglia at the thoracolumbar level and travel in the hypogastric nerve. The sensory nerves to the striated muscle of the external urethral sphincter travel in the pudendal nerve to the sacral region of the spinal cord [9]. The most important afferents for the micturition process are myelinated Aδ-fibers and unmyelinated C-fibers travelling in the pelvic nerve to the sacral spinal cord [26–28], conveying information from receptors in the bladder wall. The Aδ-fibers respond to passive distension and active contraction, thus conveying information about bladder filling [29]. The activation threshold for Aδ-fibers is 5–15 mm H_2O. This is the intravesical pressure at which humans report the first sensation of bladder filling [10]. C-fibers have a high mechanical threshold and respond primarily to chemical irritation of the bladder urothelium/suburothelium [30] or cold [31]. Following chemical irritation, the C-fiber afferents exhibit spontaneous firing when the bladder is empty and increased firing during bladder distension [30]. These fibers are normally inactive and are therefore termed “silent fibers.”

The *somatic* innervation of the urethral rhabdosphincter and of some perineal muscles (for example, compressor urethrae and urethrovaginal sphincter) is provided by the pudendal nerve. These fibers originate from sphincter motor neurons located in the ventral horn of the sacral spinal cord (levels S2–S4) in a region called Onuf’s (Onufrowicz’s) nucleus [32].

STORAGE PHASE

During the storage phase, the bladder has to relax in order to maintain a low intravesical pressure. Urine storage is regulated by two separate storage reflexes, of which one is sympathetic (autonomic) and the other is somatic [32]. The sympathetic storage reflex (pelvic-to-hypogastric reflex) is initiated as the bladder distends (myelinated Aδ-fibers) and the generated afferent activity travels in the pelvic nerves to the spinal cord. Within the spinal cord, sympathetic firing from the lumbar region (L1–L3) is initiated, which, by effects at the ganglionic level, decreases excitatory parasympathetic inputs not only to the bladder but also through postganglionic neurons that releases noradrenaline, which facilitates urine storage by stimulating mainly β_3-adrenoceptors (ARs) in the detrusor smooth muscle (see the following texts). As mentioned previously, there is little evidence for a functionally important sympathetic innervation of the human detrusor, which is in contrast to what has been found in several animal species. The sympathetic innervation of the human bladder is found mainly in the outlet region, where it mediates contraction. During micturition, this sympathetic reflex pathway is markedly inhibited via supraspinal mechanisms to allow the bladder to contract and the urethra to relax. Thus, the Aδ afferents and the sympathetic efferent fibers constitute a vesico-spinal-vesical storage reflex, which maintains the bladder in a relaxed mode while the proximal urethra and bladder neck are contracted.

In response to a sudden increase in bladder pressure, such as during a cough, laugh, or sneeze, a more rapid somatic storage reflex (pelvic-to-pudendal reflex), also called the guarding or continence reflex, is initiated. The evoked afferent activity travels along myelinated Aδ afferent nerve fibers in the pelvic nerve to the sacral spinal cord, where efferent somatic urethral motor neurons, located in the nucleus of Onuf, are activated. Afferent information is also conveyed to the periaqueductal gray (PAG) and to the pontine storage center (the L-region). Axons from these motor neurons of the nucleus of Onuf travel in the pudendal nerve and release acetylcholine, which activates nicotinic cholinergic receptors on the rhabdosphincter, which contracts. This pathway is tonically active during urine storage. During sudden abdominal pressure increases, however, it becomes dynamically active to contract the rhabdosphincter. During micturition, this reflex is strongly inhibited via spinal and supraspinal mechanisms to allow the rhabdosphincter to relax and permit urine passage through the urethra. In addition to this spinal somatic storage reflex, there is also supraspinal input from the pons, which projects directly to the nucleus of Onuf and is of importance for volitional control of the rhabdosphincter [33].

EMPTYING PHASE

Vesico-Bulbo-Vesical Micturition Reflex

Electrophysiological experiments in cats and rats provide evidence for a voiding reflex mediated through a vesico-bulbo-vesical pathway involving neural circuits in the pons, which constitute the pontine micturition center (PMC). Other regions in the brain, important for micturition, include the hypothalamus and cerebral cortex [10,34,35]. Bladder filling leads to increased activation of tension receptors within the bladder wall and thus to increased afferent activity in Aδ-fibers. These fibers project on spinal tract neurons mediating increased sympathetic firing to maintain continence as discussed earlier (storage reflex). In addition, the spinal tract neurons convey the afferent activity to more rostral areas of the spinal cord and the brain. One important receiver of the afferent information from the bladder is the PAG in the rostral brain stem. The PAG receives information both from afferent neurons in the bladder and from more rostral areas in the brain, i.e., cerebral cortex and hypothalamus. This information is integrated in the PAG and the medial part of the PMC (the M-region), which also control the descending pathways in the micturition reflex. Thus, PMC can be seen as a switch in the micturition reflex, inhibiting parasympathetic activity in the descending pathways when there is low activity in the afferent fibers and activating the parasympathetic pathways when the afferent activity reaches a certain threshold [10,35]. The threshold is believed to be set by the inputs from more rostral regions in the brain. In cats, lesioning of regions above the inferior colliculus usually facilitates micturition by elimination of inhibitory inputs from more rostral areas of the brain. On the other hand, transections at a lower level inhibit micturition. Thus, the PMC seems to be under a tonic inhibitory control. A variation of the inhibitory input to PMC results in a variation of bladder capacity. Experiments on rats have shown that the micturition threshold is regulated by, e.g., GABAergic inhibitory mechanisms in the PMC neurons [36].

Vesico-Spinal-Vesical Micturition Reflex

Spinal lesion rostral to the lumbosacral level interrupts the vesico-bulbo-vesical pathway and abolishes the supraspinal and voluntary control of micturition. This results initially in an areflexic bladder accompanied by urinary retention [10]. An automatic vesico-spinal-vesical micturition reflex develops slowly, although voiding is generally insufficient due to bladder sphincter dyssynergia, i.e., simultaneous contraction of the bladder and urethra. It has been demonstrated in chronic spinal cats that the afferent limb of this reflex is conveyed through unmyelinated C-fibers, which usually do not respond to bladder distension [30], suggesting changed properties of the afferent receptors in the bladder. Accordingly, the micturition reflex in chronic spinal cats is blocked by capsaicin, a neurotoxin that is believed to block C-fiber-mediated neurotransmission [37,38].

TARGETS FOR PHARMACOLOGICAL INTERVENTION

CNS Targets

Anatomically, several CNS regions may be involved in micturition control: supraspinal structures, such as the cortex and diencephalon, midbrain, and medulla, and also spinal structures [35,39–43]. Several transmitters and their receptors are involved in the reflexes and sites described earlier and may be targets for drugs aimed for control of micturition. Although few drugs with a CNS site of action have been developed, several agents acting on the CNS may have effects on micturition.

OPIOID RECEPTORS

Endogenous opioid peptides and corresponding receptors are widely distributed in many regions in the CNS of importance for micturition control, e.g., the PAG, the PMC, the spinal parasympathetic nucleus, and the nucleus of Onuf [44–46].

It has been well established that morphine, given by various routes of administration to animals and humans, can increase bladder capacity and eventually cause urinary retention. Given intrathecally (i.t.) to anesthetized rats and intravenously (i.v.) to humans, the µ-opioid receptor antagonist, naloxone, has been shown to stimulate micturition [47,48], suggesting that a tonic activation of µ-opioid receptors has a depressant effect on the micturition reflex.

Morphine given i.t. was effective in patients with DO due to spinal cord lesions [49] but was associated with side effects, such as nausea and pruritus. Further side effects of opioid receptor agonists comprise respiratory depression, constipation, and abuse. Attempts have been made to reduce these side effects by increasing selectivity toward one of the different opioid receptor types [50]. At least three different opioid receptors—µ, δ, and κ—bind stereospecifically with morphine and have been shown to interfere with voiding mechanisms. Theoretically, selective receptor actions, or modifications of effects mediated by specific opioid receptors, may have useful therapeutic effects for micturition control.

Tramadol is a well-known analgesic drug [51]. By itself, it is a weak µ-receptor agonist, but it is metabolized to several different compounds, some of them almost as effective as morphine at the µ-receptor. However, the drug (metabolites) also inhibits serotonin (5-HT) and noradrenaline reuptake [51]. This profile is of particular interest since both µ-receptor agonism and amine reuptake inhibition may be useful principles for treatment of OAB/DO, as shown in a placebo-controlled study with duloxetine [50].

In rats, tramadol abolished experimentally induced DO caused by cerebral infarction [52]. Tramadol also inhibited DO induced by apomorphine in rats [53]—a crude model of bladder dysfunction in Parkinson’s disease. Singh et al. [54] gave tramadol epidurally and found the drug to increase bladder capacity and compliance and to delay filling sensations without ill effects on voiding. Safarinejad and Hosseini [55] evaluated, in a double-blind, placebo-controlled, randomized study, the efficacy and safety of tramadol in patients with idiopathic DO. A total of 76 patients 18 years or older were given 100 mg tramadol sustained release every 12 hours for 12 weeks. Clinical evaluation was performed at baseline and every 2 weeks during treatment. Tramadol significantly reduced the number of incontinence periods and induced significant improvements in urodynamic parameters. The main adverse event was nausea. It was concluded that in patients with nonneurogenic DO, tramadol provided beneficial clinical and urodynamic effects. However, the study was later retracted due to “statistical errors….which undermine confidence in the results presented” (Br J Clin Pharmacol, 2013;77:1). Even if tramadol could be shown to have positive effects on LUTS/DO/OAB, it may not be a suitable drug for treatment due to side effects (nausea, constipation, dependency).

Central stimulation of δ-opioid receptors in anesthetized cats and rats inhibited micturition [56,57] and parasympathetic neurotransmission in cat bladder ganglia [58]. In humans, nalbuphine, a µ-receptor antagonist, and κ-receptor agonist, increased bladder capacity [59]. Buprenorphine (a partial µ-receptor agonist and κ-receptor antagonist) decreased micturition pressure and increased bladder capacity more than morphine [59]. These effects should be considered when the drugs are used for, e.g., pain control. In addition, further exploration of these non-µ-opioid receptor mediated actions on micturition seems motivated.

SEROTONIN (5-HT) MECHANISMS

It is well established that the lumbosacral autonomic, as well as the somatic motor nuclei (Onuf’s nuclei), receive a dense serotonergic input from the raphe nuclei, an innervation that is not subjected to the general decline in lumbosacral spinal innervation found with increasing age [60]. Multiple 5-HT receptors have been found at sites where processing of afferent and efferent impulses from and to the LUT takes place [61]. Although, as pointed out by de Groat [62], there is some evidence in the rat for serotonergic facilitation of voiding, the descending pathway is essentially an inhibitory circuit, with 5-HT as a key neurotransmitter. Thus, electrical stimulation of 5-HT-containing neurons in the caudal raphe nucleus causes inhibition of bladder contractions [63,64]. Most experiments in rats and cats indicate that activation of the central serotonergic system by 5-HT reuptake inhibitors, as well as by 5-HT_{1A} and 5-HT_2 receptor agonists, depresses reflex bladder contractions and increases the bladder volume threshold for inducing micturition [62]. 5-HT$_{1A}$ receptors are involved in multiple inhibitory mechanisms controlling the spinobulbospinal micturition reflex pathway. The regulation of the frequency of bladder reflexes is presumably mediated by a suppression of afferent input to the micturition-switching circuitry in the pons, whereas the regulation of bladder contraction amplitude may be related to an inhibition of the output from the pons to the parasympathetic nuclei in the spinal cord.

It has been discussed whether or not there is a deficiency in 5-HT behind both depression and OAB [65–67]. If there is, the question is if selective serotonin reuptake inhibitors (SSRIs) are effective for micturition control only in depressed patients, or if selective 5-HT uptake inhibition is a general principle that can be used for treatment of OAB. There are no randomized controlled clinical trials (RCTs) showing that SSRIs are useful for the treatment of OAB/DO [4,68]. In contrast, there are reports suggesting that the SSRIs in patients without incontinence actually can cause incontinence, particularly in the elderly. Patients exposed to 5-HT uptake inhibitors had an increased risk (15 out of 1000 patients) for developing UI [69]. This causes doubts over the anecdotal reports that SSRIs may be used as a general treatment for OAB. On the other hand, in an RCT, the combined 5-HT and noradrenaline reuptake inhibitor, duloxetine, was shown to be effective in patients with OAB [70].

Γ-AMINOBUTYRIC ACID MECHANISMS

γ-Aminobutyric acid (GABA) has been identified as a main inhibitory transmitter in the brain and spinal cord. GABA functions appear to be triggered by binding of GABA to its ionotropic receptors, GABA$_A$ and GABA$_C$, which are ligand-gated chloride channels, and its metabotropic receptor, GABA$_B$ [71]. Since blockade of GABA$_A$ and GABA$_B$ receptors in the spinal cord–[72,73] and brain [73,74] stimulated rat micturition, an endogenous activation of GABA$_{A+B}$ receptors may be responsible for continuous inhibition of the micturition reflex within the CNS. In the spinal cord, GABA$_A$ receptors are more numerous than GABA$_B$ receptors, except for the dorsal horn where GABA$_B$ receptors predominate [75,76].

Experiments using conscious and anesthetized rats demonstrated that exogenous GABA, muscimol (GABA$_A$ receptor agonist) and baclofen (GABA$_B$ receptor agonist), given i.v., i.t., or intracerebroventricularly inhibit micturition [73,77]. Similar effects were obtained in nonanesthetized mice [78]. Baclofen given i.t. attenuated oxyhemoglobin-induced DO in rats, suggesting that the inhibitory actions of GABA$_B$ receptor agonists in the spinal cord may be useful for controlling micturition disorders caused by C-fiber activation in the urothelium and/or suburothelium [73]. In mice, where DO was produced by intravesical citric acid, baclofen given subcutaneously had an inhibitory effect, which was blocked by the selective GABA$_B$ receptor antagonist CGP55845 [78]. Beneficial effects of baclofen have also been documented in humans with DO [79].

Stimulation of the PMC results in an immediate relaxation of the external striated sphincter and a contraction of the detrusor muscle of the bladder. Blok et al. [33] demonstrated in cats a direct pathway from the PMC to the dorsal gray commissure of the sacral cord. It was suggested that the pathway produced relaxation of the external striated sphincter during micturition via inhibitory modulation by GABA neurons of the motoneurons in the sphincter of Onuf. In rats, i.t. baclofen and muscimol ultimately produced dribbling UI [72,73], and this was also found in conscious mice given muscimol and diazepam subcutaneously [78]. Thus, normal relaxation of the striated urethral sphincter is probably mediated via GABA$_A$ receptors [73], with GABA$_B$ receptors having a minor influence on motoneuron excitability [80].

Gabapentin

Gabapentin was originally designed as an anticonvulsant GABA mimetic capable of crossing the blood–brain barrier [81]. However, its effects do not appear to be mediated through interaction with GABA receptors, and its mechanism of action is still controversial [81]. Gabapentin is also widely used not only for seizures and neuropathic pain, but for many other indications such as anxiety and sleep disorders due to its apparent lack of toxicity.

In a pilot study, Carbone et al. [82] reported on the effect of gabapentin on neurogenic detrusor activity. They found a positive effect on symptoms and a significant improvement of urodynamic parameters after treatment and suggested that the effects of the drug should be explored in further controlled studies in both neurogenic and nonneurogenic DO. Kim et al. [83] found that fourteen of 31 patients with (OAB) and nocturia, refractory to antimuscarinic treatment, improved with oral gabapentin. The drug was generally well tolerated and was considered to be an option in selective patients when conventional treatment modalities have failed. Ansari et al. [84] treated children with refractory OAB symptoms (not responding to conventional antimuscarinics) with gabapentin as an add-on and found the drug to give modest positive results. The drug was well tolerated with few adverse effects.

NORADRENALINE AND A-ADRENOCEPTORS

Noradrenergic neurons in the brain stem project to the sympathetic, parasympathetic, and somatic nuclei in the lumbosacral spinal cord. Bladder activation through these bulbospinal noradrenergic pathways may involve excitatory α_1-ARs. In rats undergoing continuous cystometry, doxazosin, given i.t., decreased micturition pressure, both in normal rats and in animals with postobstruction bladder hypertrophy [85]. The effect was much more pronounced in the animals with hypertrophies/OABs. Doxazosin given i.t., but not intra-arterially, to spontaneously hypertensive rats exhibiting bladder overactivity, normalized bladder activity [86]. It was suggested that doxazosin has a site of action at the level of the spinal cord and ganglia. However, there are no RCTs documenting positive effects of α-AR antagonists in OAB/DO [4,68].

NK1-RECEPTOR ANTAGONISTS

The main endogenous tachykinins, substance P (SP), neurokinin (NK) A, and NKB, and their preferred receptors, NK1, NK2, and NK3, respectively, have been demonstrated in various CNS regions, including those involved in micturition control [87–89]. NK1 receptor expressing neurons in the dorsal horn of the spinal cord may play an important role in DO, and tachykinin involvement via NK1 receptors in the micturition reflex induced by bladder filling has been demonstrated [90] in normal and, more clearly, rats with bladder hypertrophy secondary to bladder outlet obstruction (BOO). Capsaicin-induced DO was reduced by blocking NK1 receptor–expressing neurons in the spinal cord, using i.t. administered SP–saponin conjugate [91]. Furthermore, blockade of spinal NK1 receptor could suppress detrusor activity induced by dopamine receptor (L-DOPA) stimulation [92].

In conscious rats undergoing continuous cystometry, antagonists of both NK1 and NK2 receptors inhibited micturition, decreasing micturition pressure and increasing bladder capacity at low doses and inducing dribbling incontinence at high doses. This was the most conspicuous in animals with outflow obstruction [93]. Intracerebroventricular administration of NK1- and NK2-receptor antagonists to awake rats' suppressed detrusor activity induced by dopamine receptor (L-DOPA) stimulation [94]. Taken together, available information suggests that spinal and supraspinal NK1 and NK2 receptors may be involved in micturition control.

Aprepitant, an NK1-receptor antagonist used for treatment of chemotherapy-induced nausea and vomiting [95], significantly improved symptoms of OAB in postmenopausal women with a history of urgency incontinence or mixed incontinence (with predominantly urgency UI), as shown in a well-designed pilot RCT [96]. The primary end point was percent change from baseline in average daily micturitions assessed by a voiding diary. Secondary end points included average daily total UI and urgency incontinence episodes and urgency episodes. Aprepitant significantly decreased the average daily number of micturitions compared with placebo at 8 weeks. The average daily number of urgency episodes was also significantly reduced compared to placebo and so were the average daily number of urgency incontinence and total UI episodes, although the difference was not statistically significant. Aprepitant was generally well tolerated and the incidence of side effects, including dry mouth, was low. The results of this initial proof of concept study suggest that NK1-receptor antagonism holds promise as a potential treatment approach for OAB. In another RCT including 476 patients with OAB, the effects of the selective NK1-receptor antagonist, serlopitant (several doses), were compared with those of tolterodine ER 4 mg [97]. Tolterodine was numerically superior to all doses of serlopitant in mean micturitions per day and secondary end points (urgency, total incontinence, urge incontinence episodes, and incidence of dry mouth), and the authors concluded that even NK1-receptor antagonists may have a role in the treatment of OAB, but serlopitant did not offer advantages in efficacy compared to tolterodine. In a phase II RCT, Haab et al. [98] assessed the efficacy and safety of the NK1-receptor antagonist, netupitant, in patients with OAB. The study failed to demonstrate superiority of netupitant versus placebo in decreasing OAB symptoms.

It seems as even if NK1-receptor antagonists may have a beneficial effect on OAB symptoms, none of the drugs tested have shown any efficacy advantages over standard therapy with antimuscarinics.

DOPAMINE AND DOPAMINE RECEPTORS

Many patients with Parkinson’s disease have neurogenic DO and other functional disturbances of detrusor function [99–101], possibly as a consequence of nigrostriatal dopamine depletion and failure to activate inhibitory D1 receptors [101,102]. Sillén et al. [103] showed that apomorphine, which activates both D1 and D2 receptors, induced bladder overactivity in anesthetized rats via stimulation of central dopaminergic receptors. The effects were abolished by infracollicular transection of the brain and by prior intraperitoneal administration of the centrally acting dopamine receptor blocker, spiroperidol. Kontani et al. [104,105] suggested that the bladder overactivity induced by apomorphine in anesthetized rats resulted from synchronous stimulation of the micturition centers in the brain stem and spinal cord and that the response was elicited by stimulation of both dopamine D1 and D2 receptors. Kitta et al. [106] tried to elucidate the role of extracellular dopamine, glutamate, and GABA by in vivo microdialysis in the PAG during cystometry, as well as to evaluate the dopaminergic system’s role in the micturition reflex of an animal model of Parkinson’s disease. Based on their results, they suggested that the micturition reflex is under tonic dopaminergic regulation through D1 receptors, in which a GABAergic mechanism is involved, and that the bladder overactivity observed in 6-OHDA-lesioned rats may be caused by dysfunction of GABAergic regulation underlying the micturition reflex.

The effect of dopaminergic drugs on micturition has produced conflicting results [101], and Winge et al. [107] found that the effect on micturition of treatment with dopaminergic drugs in Parkinson’s disease was unpredictable. Studies have shown that in early phases of Parkinson’s disease, a single dose of levodopa exacerbates DO [108]. In contrast, in advanced stages of the disease, the drug improved bladder storage function [109].

The effects on micturition of various dopamine receptor active drugs used for, e.g., different psychiatric conditions, should not be neglected.

Peripheral Targets

Possible peripheral targets for pharmacological intervention may be (1) the efferent neurotransmission, (2) the smooth muscle itself, including ion channels and intracellular second messenger systems, and (3) the afferent neurotransmission. Although many effective drugs are available for these target systems, most of them are less useful in the clinical situation due to the lack of selectivity for the LUT, which may result in intolerable side effects. Thus, a main task is to find systems or receptors, more or less specific for the LUT, which can be manipulated without disturbing other systems in the body, or alternatively, to design drugs in a way that results in higher tissue concentrations in the LUT than elsewhere in the body.

MUSCARINIC RECEPTORS

Muscarinic receptors comprise five subtypes, encoded by five distinct genes [110]. The five gene products correspond to pharmacologically defined receptors, and M_1–M_5 is used to describe both the molecular and pharmacological subtypes. In the human bladder, the mRNAs for all muscarinic receptor subtypes have been demonstrated [111,112], with a predominance of mRNAs encoding M_2 and M_3 receptors [111,113]. These receptors are also functionally coupled to G-proteins, but the signal transduction systems vary [114–119].

Detrusor smooth muscle contains muscarinic receptors of mainly the M_2 and M_3 subtypes [114–119]. The M_3 receptors in the human bladder are believed to be the most important for detrusor contraction. Jezior et al. [120] suggested that muscarinic receptor activation of detrusor muscle includes both nonselective cation channels and activation of Rhokinase. Supporting a role of Rho-kinase in the regulation of rat detrusor contraction and tone, Wibberley et al. [121] found that Rho-kinase inhibitors (Y-27632, HA 1077) inhibited contractions evoked by carbachol without affecting the contraction response to KCl. They also demonstrated high levels of Rho-kinase isoforms (I and II) in the bladder. Schneider et al. [119] concluded that carbachol-induced contraction of human urinary bladder is mediated via M_3 receptors and largely depends on Ca^{2+} entry through nifedipine-sensitive channels and activation of the Rho-kinase pathway. Thus, the main pathway for muscarinic receptor activation of the detrusor via M_3 receptors may be calcium influx via L-type calcium channels and increased sensitivity to calcium of the contractile machinery produced via inhibition of myosin light chain phosphatase through activation of Rho-kinase [122].

The functional role for the M_2 receptors has not been clarified, but it has been suggested that M_2 receptors may oppose sympathetically mediated smooth muscle relaxation, mediated by β-ARs [123]. M_2 receptor stimulation may also activate nonspecific cation channels [124] and inhibit ATP-sensitive K^+ (K_{ATP}) channels through activation of protein kinase C [125,126]. In certain disease states, M_2 receptors may contribute to contraction of the bladder. Thus, in the denervated rat bladder, M_2 receptors or a combination of M_2- and M_3-mediated contractile responses and the two types of receptor seemed to act in a facilitatory manner to mediate contraction [127–129]. In obstructed, hypertrophied rat bladders, there was an increase in total and M_2 receptor density, whereas there was a reduction in M_3 receptor density [130]. The functional significance of this change for voiding function has not been established. Pontari et al. [131] analyzed bladder muscle specimens from patients with neurogenic bladder dysfunction to determine whether the muscarinic receptor subtype mediating contraction shifts from M_3 to the M_2 receptor subtype, as found in the denervated, hypertrophied rat bladder. They concluded that whereas normal detrusor contractions are mediated by the M_3 receptor subtype, in patients with neurogenic bladder dysfunction, contractions can be mediated by the M_2 receptors.

Muscarinic receptors may also be located on the presynaptic nerve terminals and participate in the regulation of transmitter release. The inhibitory prejunctional muscarinic receptors have been classified as M_4 in the human bladder [132]. Prejunctional facilitatory muscarinic receptors appear to be of the M_1 [133]. The muscarinic facilitatory mechanism seems to be upregulated in hyperactive bladders from chronic spinal cord–transected rats. The facilitation in these preparations is primarily mediated by M_3 muscarinic receptors [133,134].

Muscarinic receptors have also been demonstrated on the urothelium/suburothelium. The porcine urothelium was found to express a high density of muscarinic receptors, even higher than the bladder smooth muscle [135], and, in the rat and human urothelium, the receptor proteins and mRNAs, respectively, for all muscarinic receptor subtypes (M_1–M_5), were demonstrated [136]. Mansfield et al. [137] found, using RT-PCR analysis, an abundant expression of muscarinic M_2 receptors in the human bladder mucosa. These receptors may occur at other locations than the urothelium, e.g., on suburothelial interstitial cells [138,139].

The suburothelial nerve plexus is close to the urothelium [140–142]. The urothelium, as mentioned previously, has been suggested to work as a mechanosensory conductor, and in response to, e.g., distension, it releases ATP affecting underlying afferent nerve fibers via purinoceptors [143,144]. This may consequently modify the afferent response of the bladder [145,146]. ACh is produced in the urothelium, but the mechanism behind its release does not seem to involve vesicular exocytosis [147,148]. The organic cation transporter 3 subtype has been demonstrated in and suggested to be involved in the nonneuronal release from rat urothelium [148].

ADRENERGIC RECEPTORS

α-Adrenoceptors

α-ARs may have effects on different locations in the bladder: the detrusor smooth muscle, the detrusor vasculature, the afferent and efferent nerve terminal and intramural ganglia. For some of these possible sites, only fragmentary information is available. Most investigators agree on that there is a low expression of these receptors in the detrusor muscle [149–152]. In the human bladder studies, Malloy et al. [149] found that 2/3 of the α-AR mRNA expressed was α_{1D}, there was no α_{1B}, and 1/3 was α_{1A}.

Nomiya and Yamaguchi [153] confirmed the low expression of α-AR mRNA in normal human bladder and further demonstrated that there was no upregulation of any of the adrenergic receptors with obstruction. In addition, in functional experiments, they found a small response to phenylephrine at high drug concentrations with no difference between normal and obstructed bladders. Thus, in the obstructed human bladder, there seemed to be no evidence for α-AR upregulation. This finding was challenged by Bouchelouche et al. [154] who found an increased response to α_1-AR stimulation in obstructed human bladders. If there is a change of sensitivity to α-AR stimulation in the obstructed bladder of clinical importance (influencing the response to α-AR blockers) remains to be established.

All subtypes of α-ARs can be found in different parts of the human vascular tree, and they all mediate contraction. The expression varies with vessel bed and increases with age. In the bladder, the function of the detrusor muscle is dependent on the vasculature and the perfusion. Hypoxia induced by partial outlet obstruction is believed to play a major role in both the hypertrophic and degenerative effects of partial outlet obstruction. Das et al. [155] investigated in rats whether doxazosin affected blood flow to the bladder and reduced the level of bladder dysfunction induced by partial outlet obstruction. They found that 4 weeks treatment with doxazosin increased bladder blood flow in both controlled and obstructed rats. Furthermore, doxazosin treatment reduced the severity of the detrusor response to partial outlet obstruction. Thus, doxazosin could reduce the increase in bladder weight in obstructed animals, which could be one of the mechanisms that contributed to a positive effect on DO caused by the obstruction.

It is well documented that α_1-AR antagonists can ameliorate LUTS in men [68,156,157]. Currently used α_1-AR antagonists are considered effective for treatment of both storage and voiding symptoms in men with LUTS associated with or suggestive of BPH [157]. However, in a study where tamsulosin was given alone, or together with tolterodine, to male patients with LUTS and OAB symptoms, monotherapy with the drug was not effective [158].

In females, treatment with OAB, α_1-AR antagonists seem to be ineffective. In an RCT, comprising 364 women with OAB, no effect of tamsulosin vs. placebo could be demonstrated [159]. On the other hand, voiding symptoms in women with functional outflow obstruction, or LUTS, were treated (with modest success) with an α_1-AR antagonist [160,161]. It should be remembered that in women these drugs may produce stress incontinence [162].

In patients with neurogenic DO, treatment with α_1-AR antagonists was moderately successful [163].

β-Adrenoceptors

It has been known for a long time that isoprenaline, a nonsubtype selective β-AR agonist, can relax the bladder smooth muscle [18]. Even if the importance of β-ARs for human bladder function still remains to be established [164], this does not exclude that they can be useful therapeutic targets. All three subtypes of β-ARs (β_1, β_2, and β_3) can be found in the detrusor muscle of most species, including humans [150,164] and also in the human urothelium [165]. However, the expression of β_3-AR mRNA [150,153] and functional evidence indicate a predominant role for this receptor in both normal and neurogenic bladders [150,166,167]. The human detrusor also contains β_2-ARs, and most probably, both receptors are involved in the physiological effects (relaxation) of noradrenaline in the bladder [150,164]. β_3-AR agonists have a pronounced effect on spontaneous contractions of isolated detrusor muscle [168], which may be the basis for their therapeutic effects in OAB/DO.

It is generally accepted that β-AR-induced detrusor relaxation is mediated by activation of adenylyl cyclase with the subsequent formation of cAMP [169]. However, there is evidence suggesting that in the bladder K^+ channels, particularly calcium-activated K^+ (BK_{ca}) channels, may be involved in β-AR-mediated relaxation independent of cAMP [170–173].

The in vivo effects of β_3-AR agonists on bladder function have been studied in several animal models. It has been shown that β_3-AR agonists increase bladder capacity with no change in micturition pressure and residual volume [174–177]. For example, Hicks et al. [178] studied the effects of the selective β_3-AR agonist, GW427353, in the anesthetized dog and found that the drug evoked an increase in bladder capacity under conditions of acid-evoked bladder hyperactivity, without affecting voiding. Aizawa et al. [179] showed that another selective β_3-AR agonist, mirabegron, could inhibit filling-induced activity in both mechanosensitive Aδ- and C-fiber primary bladder afferents of the rat bladder.

Mirabegron is the only β_3-AR selective agonist approved for treatment of OAB. Several pharmaceutical companies are developing β_3-AR selective agonists for treatment of this disorder [180,181]; however, so far, mirabegron is the only β_3-AR selective agonist approved for treatment of OAB.

Pharmacokinetics

Mirabegron is rapidly absorbed after oral administration, and maximum plasma concentration (T_{max}) is reached in about 2 hours [182,183]. The terminal elimination half-life ($t_1/2$) is approximately 23–25 hours. The drug circulates in the plasma as the unchanged active form and inactive metabolites. Most of an administered dose is excreted in urine, mainly as the unchanged form, and one-third is recovered in feces, almost entirely as the unchanged form [184]. Mirabegron is highly lipophilic and is metabolized in the liver via multiple pathways, mainly by cytochrome (CY) P450, CYP3A4, and CYP2D6 [185–187].

Mechanism(s) of Action

Filling of the bladder initiates activity in “in-series”-coupled, low-threshold mechanoreceptive (Aδ) afferents [188]. This implies that, if the compliance of the bladder is increased, the response to distension is decreased and, to recruit sufficient afferent activity needed to initiate micturition, greater filling volumes are needed—thus, bladder capacity increases. One determinant of bladder compliance is the spontaneous (autonomous) bladder activity during filling. Experimental studies of human [168,189,190], rat [191–193], and monkey [194] bladder have documented inhibitory effects of β3-AR agonists on autonomous activity in vitro and on “nonvoiding contractions” in vivo. Mirabegron inhibited only nonvoiding activity in rat, while tolterodine (antimuscarinic) inhibited nonvoiding activity as well as the amplitude of voiding contractions [191]. Since the voiding contraction is caused by a massive release of contractant transmitters (ACh and ATP), this may be the reason why bladder emptying does not seem to be impaired by β_3-AR agonists [195].

Clinical Use

Efficacy: Mirabegron has been evaluated in three pivotal phases, 12-week RCTs in patients with OAB symptoms of urgency UI, urgency, and urinary frequency [196–198]. These trials showed the drug to be effective and very well tolerated. In a urodynamic safety study on 200 male patients with BOO and LUTS, the effects of mirabegron 50 or 100 mg once daily for 12 weeks have been reported [199]. Mirabegron did not adversely affect flow rate, detrusor pressure at maximum flow rate, or bladder contractile index and was well tolerated.

The safety and efficacy of long-term administration of mirabegron 50 and 100 mg was compared to that of tolterodine in a 12-month, 3-armed, parallel group study (no placebo arm). A total of 812 (50 mg) and 820 (100 mg) patients were randomized to receive mirabegron, and 812 patients received tolterodine ER 4 mg. The primary variable was incidence and severity of treatment-emergent adverse effects, and secondary variables were change from baseline at months 1, 3, 6, 9, and 12 in key OAB symptoms. Both mirabegron and tolterodine improved key OAB symptoms from the first measured time point of 4 weeks, and efficacy was maintained throughout the 12-month treatment period [200].

Tolerability and Adverse Effects

In the clinical studies performed, the tolerability of mirabegron has been good as well as the adverse effect close to those of placebo [201]. For example, in the study of Khullar et al. [197], the incidence of adverse effects for the placebo and mirabegron 50 and 100 mg groups were 50.1%, 51.6%, and 46.9%, respectively. The most common (≥3%) adverse effects in any treatment group were hypertension (6.6%, 6.1%, and 4.9%, respectively), urinary tract infection (1.8%, 2.7%, and 3.7%), headache (2.0%, 3.2%, and 3.0%), and nasopharyngitis (2.9%, 3.4%, and 2.5%). The incidence of dry mouth was similar in the placebo and mirabegron groups (2.6% vs. 2.8%) and lower than observed in patients receiving tolterodine SR (10.1%). The incidence of constipation was similar in all treatment groups (placebo 1.4%, mirabegron 1.6%), including tolterodine (2.0%).

One concern with the use of β_3-AR agonists has been the possibility of negative cardiovascular effects. However, in the studies on OAB, patients referred to the mean increases (compared to placebo) in systolic/diastolic blood pressure after therapeutic doses of mirabegron once daily, which was approximately 0.5–1 mmHg and reversible upon discontinuation of treatment. In a study on healthy volunteers, mirabegron increased *heart rate* (HR) in a dose-dependent manner. Maximum mean increases in HR from baseline for the 50, 100, and 200 mg dose groups compared to placebo were 6.7 beats per minute (bpm), 11 bpm, and 17 bpm, respectively, in healthy volunteers [202]. However, in the clinical efficacy and safety studies, the change from baseline in mean pulse rate for mirabegron 50 mg was approximately 1 bpm and reversible upon discontinuation of treatment.

The cardiac safety of mirabegron was evaluated in a thorough QT/QTc (HR-corrected QT interval) study, including supratherapeutic dose. This was a randomized, placebo-, and active-controlled (moxifloxacin 400 mg), four-treatment-arm, parallel crossover study in 352 healthy subjects [202]. The effect of multiple doses of mirabegron 50, 100, and 200 mg once daily on QTc interval was studied; mirabegron did not cause QTcI prolongation at the 50 mg therapeutic and 100 mg supratherapeutic doses in either sex. The drug prolonged QTcI interval at the 200 mg supratherapeutic dose (upper one-sided 95% CI >10 ms) in females, but not in males.

Even if the cardiovascular effects of mirabegron observed in clinical studies have been minimal and clinically not relevant, effects on heart rate and blood pressure need to be monitored when the drug is generally prescribed and patients with cardiovascular morbidities are treated.

A combination of an antimuscarinic and mirabegron (or other β_3-AR agonists) seems rationale and theoretically attractive. Abrams et al. [203] evaluated the efficacy of combinations of solifenacin/mirabegron compared with solifenacin 5 mg monotherapy in a phase II, factorial design, randomized, double-blind, parallel-group, and placebo- and monotherapy-controlled trial including 1306 male and female (66.4%) patients with OAB aged ≥ 18 years. They were randomized to 12 weeks of treatment in 1 of 12 groups: 6 combination groups (solifenacin 2.5, 5, or 10 mg plus mirabegron 25 or 50 mg), 5 monotherapy groups (solifenacin 2.5, 5, or 10 mg or mirabegron 25 or 50 mg), or placebo. It was found that compared with solifenacin 5 mg monotherapy, all combinations with solifenacin 5 or 10 mg significantly improved mean volume voided per micturition (the primary end point), micturition frequency, and urgency. All combinations were well tolerated, with no important additional safety findings compared with monotherapy or placebo.

PHOSPHODIESTERASE INHIBITORS

Drugs stimulating the generation of cAMP are known to relax smooth muscles, including the detrusor [164,169]. It is also well established that drugs acting through the NO/cGMP system can relax the smooth muscle of the bladder outflow region [164]. Use of phosphodiesterase (PDE) inhibitors to enhance the presumed cAMP- and cGMP-mediated relaxation of LUT smooth muscles (detrusor prostate, urethra) should then be a logical approach [204]. There are presently 11 families of PDEs, some of which preferentially hydrolyze either cAMP or cGMP [204].

As a basis for PDE inhibitor treatment of LUTS, Uckert et al. [205] investigated human bladder tissue, revealing messenger RNA for PDEs 1A, 1B, 2A, 4A, 4B, 5A, 7A, 8A, and 9A; most of these PDEs preferably inhibit the breakdown of cAMP. In vitro, human detrusor muscle responded poorly to sodium nitroprusside and to agents acting via the cGMP system [206]. However, significant relaxation of human detrusor muscle, paralleled by increases in cyclic nucleotide levels, was induced by papaverine, vinpocetine (a low affinity inhibitor of PDE 1), and forskolin (stimulating the generation of cAMP), suggesting that the cAMP pathway and PDE 1 may be important in regulation of detrusor smooth muscle tone [207]. Significant dose-dependent relaxations were also induced by human cAMP analogs [207]. With these studies as a background, Truss et al. [206] presented preliminary clinical data with vinpocetine in patients with urgency/urgency incontinence or low compliance bladders and not responding to standard antimuscarinic therapy. This initial open pilot study suggested a possible role for vinpocetine in the treatment of OAB. However, the results of a larger RCT in patients with DO showed that vinpocetine only showed statistically significant results for one parameter [207]. Studies with other PDE 1 inhibitors than vinpocetine (which may not be an optimal drug for elucidation the principle) do not seem to have been performed.

PDE 4 (which also preferably hydrolyzes cAMP) has been implicated in the control of bladder smooth muscle tone. PDE 4 inhibitors reduced the in vitro contractile response of guinea pig [208] and rat [209,210] bladder strips and also suppressed rhythmic bladder contractions of the isolated guinea pig bladder [211]. Previous experiences with selective PDE 4 inhibitors showed emesis to be a dose-limiting effect [212]. If this side action can be avoided, PDE 4 inhibition seems to be a promising approach.

NO has been demonstrated to be an important inhibitory neurotransmitter in the smooth muscle of the urethra and its relaxant effect is associated with increased levels of cyclic GMP [1]. However, few investigations have addressed the cAMP- and cGMP-mediated signal transduction pathways and its key enzymes in the mammalian urethra. Morita et al. [213] examined the effects of isoproterenol, prostaglandin E_1 and E_2, and SNP on the contractile force and tissue content of cAMP and cGMP in the rabbit urethra. They concluded that both cyclic nucleotides can produce relaxation of the urethra. Werkström et al. [214] characterized the distribution of PDE 5, cGMP, and PKG1 in female pig and human urethra and evaluated the effect of pharmacological inhibition of PDE 5 in isolated smooth muscle preparations. After stimulation with the NO donor, DETA NONOate, the cGMP-immunoreactivity (IR) in urethral and vascular smooth muscles increased. There was a wide distribution of cGMP- and vimentin-positive interstitial cells between pig urethral smooth muscle bundles. PDE 5 IR could be demonstrated not only within the urethral and vascular smooth muscle cells but also in vascular endothelial cells that expressed cGMP-IR. Nerve-induced relaxations of urethral preparations were enhanced at low concentrations of sildenafil, vardenafil, and tadalafil, whereas there were direct smooth muscle relaxant actions of the PDE 5 inhibitors at high concentrations.

The observation that patients treated for erectile dysfunction with PDE 5 inhibitors had an improvement of their LUTS has sparked a new interest in using these drugs also for treatment of LUTS and OAB. After the report in an open study [215] that treatment with sildenafil appeared to improve urinary symptom scores in men with ED and LUTS, this observation has been confirmed in several well-designed and conducted RCTs [216–218].

The effects of PDE 5 inhibitors for treatment of male LUTS have been well summarized in several previous reviews [219,220].

The mechanism of action of tadalafil in relieving LUTS has not been established, even if improvement of the bladder blood flow to the LUT has been suggested [221,222]. In an RCT, Pinggera et al. [223], using transrectal ultrasonography, compared the effects of tadalafil 5 mg/day and placebo given for 8 weeks to men with moderate to severe LUTS/BPH. They found no differences between the treatments but did not exclude that changes in blood flow may have occurred, which for several reasons could not be detected. Interestingly, previously, Pinggera et al. [224], using transrectal color Doppler ultrasound, quite convincingly showed that tamsulosin could increase perfusion to the LUT.

ION CHANNELS

Ion channels are important regulators of the cell function. Located within the plasma membrane, they control the permeability of different ions. The two most thoroughly investigated classes of ion channels are calcium channels and potassium channels [164].

Calcium Channels

Calcium is a key component for cell function in many cells. In smooth muscle, increased intracellular calcium concentrations activate the contractile mechanisms, and in nerve terminals, calcium influx in response to action potentials is an important mechanism for neurotransmitter release. Calcium channels can be divided into at least four different subtypes: L, N, P, and Q channels. The calcium channels present in smooth muscles are L-type (dihydropyridine sensitive) calcium channels and seem to be involved in contraction of the human bladder irrespective of the mode of activation [225]. A decrease of the membrane potential (depolarization) increases the open probability for calcium channels, thereby increasing the calcium influx. Thus, the channels are dependent on the membrane potential and are termed voltage-operated calcium channels (VOCC). Elevated intracellular calcium levels are also believed to initiate release of calcium from intracellular stores, a mechanism called calcium-induced calcium release [226,227]. Thus, regulation of the intracellular calcium concentration in smooth muscle cells is one conceivable way to modulate bladder contraction. Dihydropyridines, e.g., nifedipine, have a potent inhibitory effect on isolated detrusor muscle. Inhibitory effects have also been demonstrated on experimentally induced contractions under in vivo conditions in rats and clinically in patients with DO [18]. However, therapeutically, there is no evidence that calcium antagonists have any useful effects in the treatment of OAB/DO [4,68].

Potassium Channels

Potassium channels represent another mechanism to modulate the excitability of the smooth muscle cells. Under normal conditions, the resting membrane potential in smooth muscle cells is determined predominantly by the membrane conductivity for potassium ions. Increased potassium conductivity will lower the membrane potential by increasing the potassium efflux. As a consequence, this will increase the threshold for opening of VOCC and initiation of contraction. There are several different types of K^+ channels, and at least two subtypes have been found in the human detrusor, K_{ATP} and large conductance BK_{Ca}. Studies on the isolated human detrusor muscle and on the bladder tissue from several animal species have demonstrated that K^+-channel openers reduce spontaneous contractions as well as contractions induced by carbachol and electrical stimulation [164]. However, the lack of selectivity of presently available K^+-channel blockers for the bladder versus the vasculature has thus far limited the use of these drugs. No effects of cromakalim or pinacidil on the bladder were found in studies on patients with spinal cord lesions or detrusor instability secondary to outflow obstruction [228,229]. Some new K^+-channel openers have been developed and claimed to have selectivity toward the bladder [164]. However, so far there is no evidence that K^+-channel openers is an option for treatment of OAB/DO [4,68].

AFFERENT SIGNALING MECHANISMS

Urothelium

Recent evidence suggests that the urothelium may serve as a mechanosensor, which, by producing NO, ATP, ACh, and other mediators, can control the activity in afferent nerves and thereby the initiation of the micturition reflex [230–232]. Low pH, high K^+, increased osmolality, and low temperatures can all influence afferent nerves, possibly via effects on the "vanilloid" (TRPV1) receptor, which is expressed both in afferent nerve terminals and in the epithelial cells that line the bladder lumen [233,234]. A network of interstitial cells (interstitial cells of Cajal [ICCs]), extensively linked by Cx43-containing gap junctions, was found to be located beneath the urothelium in the human bladder [235,236]. This interstitial cellular network was suggested to operate as a functional syncytium, integrating signals and responses in the bladder wall. The firing of suburothelial afferent nerves and the threshold for bladder activation may be modified by both inhibitory (e.g., NO) and stimulatory (e.g., ATP, ACh, tachykinins, prostanoids) mediators. ATP, generated by the urothelium, has been suggested as an important mediator of urothelial signaling [230,231]. Supporting such a view, intravesical ATP induces DO in conscious rats [237]. Furthermore, mice lacking the $P2X_3$ receptor were shown to have hypoactive bladders [144,238].

There seem to be other, thus far unidentified, factors in the urothelium that could influence bladder function [1]. Fovaeus et al. [239] found a previously unrecognized nonadrenergic, nonnitrergic, nonprostanoid inhibitory mediator is released from the rat urinary bladder by muscarinic receptor stimulation. However, it was not clear whether this factor came from the detrusor muscle or from both the bladder and the urothelium. Data have been presented suggesting the presence of a diffusible, urothelium-derived inhibitory factor, which could not be identified, but appeared to be neither nitric oxide, a cyclooxygenase product, a catecholamine, adenosine, GABA nor any substance sensitive to apamin. The identity and possible physiological role of the unknown factor remains to be established and should offer an interesting field for further research [135,240]. This mechanism can be involved in the pathophysiology of the OAB syndrome and DO and thus seem to be interesting targets for pharmacological intervention.

Myocytes

Myogenic activity can be defined as the ability of a smooth muscle cell to generate mechanical activity independent of external stimuli [164,241]. In the individual myocyte, contractile activity is preceded and initiated by an action potential, which is calcium driven [242]. It has been suggested that the detrusor muscle is arranged into units (modules), which are circumscribed areas of the muscle [243]. These modules show contractile activity during the filling phase of the micturition cycle and might be controlled by several factors including a peripheral myovesical plexus, consisting of intramural ganglia and ICC [244,245]. Intercellular connections may contribute to not only module control but also locally generated mediators. Kinder and Mundy [246] found that spontaneous contractile activity developed more often in muscle strips from overactive than normal bladders, a finding underlined by Brading [247] and confirmed by Mills et al. [248]. Turner and Brading [249] discussed the occurrence of "patchy denervation" in cases of DO with subsequent changes of the smooth muscle cells, e.g., supersensitivity to ACh. Such an increased sensitivity has been demonstrated in smooth muscle preparations from patients with idiopathic and neurogenic DO [250]. It has been reported that suburothelial ICC respond to purinergic stimulation by firing Ca^{2+} transients [251]. Interestingly, these suburothelial ICC may be able to affect the activity of the detrusor myocytes [252–254]. The frequency of the spontaneous rhythmic contractions of isolated detrusor smooth muscle preparations seems to vary between species and is probably also dependent on experimental factors [164,244]. Characteristically, these contractions are resistant to the Na-channel blocker (TTX) and cannot be blocked by hexamethonium, atropine, α-AR blockers, β-AR blockers, or suramin, apparently excluding direct involvement of nerves and nerve-released transmitters [164]. Contractions can be effectively inhibited by L-type Ca^{2+}-channel blockers and K^+-channel openers, supporting the important role of L-type Ca^{2+} channels for the activity. It cannot be excluded that these spontaneous contractions generate part of the afferent activity ("afferent noise") during filling of the bladder [255].

SENSORY NERVES AND VANILLOID RECEPTORS

Intravesical administration of capsaicin or resiniferatoxin (RTX) has been shown to increase bladder capacity and decrease urge incontinence in patients with neurogenic, as well as nonneurogenic forms of DO [4,68,256]. Vanilloids are exogenous ligands of vanilloid receptor type 1 (TRPV1 or VR1), an ion channel present in the membrane of type C primary afferent nerve fibers innervating the bladder wall and the periurethral zone of the prostate gland [257]. This receptor, which plays a key role in inflammatory pain perception and control of the micturition reflex [257,258], may be upregulated by nerve growth factor (NGF), a neurotrophic molecule detected in high concentrations in overactive detrusors generated by chronic BOO [259]. Vanilloids, by reducing uptake of NGF through sensory neurons, may counteract TRPV1 upregulation. In addition, vanilloids decrease the response of already expressed TRPV1 receptors (desensitization) [258].

Important sensory information from the prostate and bladder is conveyed by C-fibers. Local anesthesia of the prostatic urethra was shown to increase bladder volume to first sensation to urinate and maximal bladder capacity and also to reduce or abolish DO, in patients with benign prostatic enlargement [260]. Likewise, intravesical lidocaine was shown to reduce involuntary detrusor contractions in patients with DO [261]. Lidocaine is more effective to anesthetize C- than Aδ-fibers supporting the contribution of prostate and bladder C-fiber input to abnormal detrusor activity.

The ice water test triggers a capsaicin-sensitive spinal micturition reflex mediated by unmyelinated C-fibers in the bladder and urethra [262]. Chai et al. [263] demonstrated a positive ice water test in 71% of subjects with BOO (12 of 17), which was significantly higher than the 7% positive ice water test rate in nonobstructed subjects (3 of 44). The authors suggested this to be caused by an enhanced spinal micturition reflex, possibly due to plasticity of bladder afferents after BOO. If this is the case, intravesical treatment of patients with LUTS associated with BOO with intravesical vanilloids, by desensitizing C-fibers, would be an interesting approach. Two preliminary studies with intravesical RTX suggested that this may be the case [264,265]. In a controlled study on neurogenic DO, Silva et al. [266] concluded that the drug was effective for treatment of this disorder. Several other studies have arrived at divergent results, some claiming good effects and others not demonstrating any superiority of RTX over placebo [4,68].

Despite some evidence of efficacy in LUTS/OAB/DO, capsaicin and RTX are no longer widely used [4,68]. Side effects (pain) and the lack of stable RTX preparations, available for easy bladder instillation, will make further investigation of the compound difficult. Different origins of the vanilloid and different ways for preparation and storage of the solutions might have caused substantial differences in the amount of active compound effectively administered to the patients. In addition, RTX adheres to plastics, another reason to the discrepancies that have been observed among RTX studies.

BOTULINUM TOXIN

Botulinum toxin (BoNT) is a neurotoxin produced by *Clostridium botulinum*. BoNT comprises seven subtypes, of which subtype A (BoNT-A), which has the longest duration of action, is clinically the most important. BoNT-A is available in three different commercial forms: onabotulinumtoxinA, abobotulinumtoxinA, and incobotulinumtoxinA. Although there are differences in potency between the forms, there are no reasons to believe that their basic mechanism of action is different. The potency of each one is usually expressed in units (U); however, the doses are not interchangeable. Unfortunately, clinical dose conversion studies for the LUT are not available. Most of the intravesical experience reported on BoNT-A deals with Botox®.

BoNT consists of a heavy and a light chain linked by a disulphide bond. In the synaptic cleft, the toxin binds to synaptic vesicle protein [267] through its heavy chain and is internalized by the nerve terminal. Upon cleavage, the light chain is released in the cytosol, where it impedes binding of neurotransmitter-containing synaptic vesicles to the plasma membrane. The rationale for using botulinum toxin to treat human DO is based on the assumption that effects of the toxin on skeletal muscle would be replicated in bladder smooth muscle [268,269] and that detrusor muscle paralysis would reduce the symptoms of bladder overactivity [270]. BoNT has been currently developed as a second-line treatment option (following failure of, or intolerance to, appropriate antimuscarinic therapy) for patients with NDO with UI or other neurogenic OAB symptoms and who are able and willing to perform CIC. Efficacy has also been demonstrated in spinal cord injury patients with detrusor-sphincter dyssynergia [270–273].

The first report of the application of BoNT-A in NDO appeared in 2000 [268]. Since then, several RCTs have documented the clinical effects of onabotulinumtoxinA in neurogenic and idiopathic DO, where the drug decreases incontinence episodes, frequency, and urgency and improves quality of life [274–277]. The drug was also shown to be effective in patients with idiopathic OAB [278]. Successful treatment of OAB symptoms with BoNT-A does not appear to be related to the existence of DO. No differences in outcomes were found between those with and those without baseline DO [279,280].

Nitti et al. [278] reported results of the first large (n = 557) phase III placebo-controlled trial of onabotulinumtoxinA in patients with OAB. To be included, patients should have ≥3 urgency UI episodes in 3 days and ≥8 micturitions/day. They were randomized 1:1 to receive intradetrusor injection of onabotulinumtoxinA 100U or placebo (saline). Coprimary end points were changed from baseline in UI episodes/day and proportion of patients with a positive response on the treatment benefit scale at week 12 posttreatment. Secondary end points included other OAB symptoms and health-related quality of life. OnabotulinumtoxinA significantly reduced the daily frequency of UI episodes versus placebo (−2.65 vs. −0.87, $p < 0.001$) and 22.9% vs. 6.5% of patients became completely continent. A larger proportion of onabotulinumtoxinA-treated patients than placebo reported a positive response on the TBS (60.8% vs. 29.2%, $p < 0.001$). All other OAB symptoms improved versus placebo ($p \leq 0.05$). OnabotulinumtoxinA improved patients' health-related quality of life across multiple measures ($p < 0.001$).

The finding that onabotulinumtoxinA 100U was consistently effective with a two- to fourfold improvement over placebo in all symptoms of OAB is important: an effect of this magnitude versus placebo does not seem to have been reported previously with antimuscarinics or β_3-AR agonists.

Adverse Effects

In the study by Nitti et al. [278], the majority of adverse effects occurred in the first 12 weeks (15.5% with onabotulinumtoxinA vs. 5.9% with placebo). The most frequently reported adverse effect was uncomplicated urinary tract infection with no upper urinary tract involvement. Other adverse effects were dysuria (12.2%), bacteriuria (5.0%), and urinary retention (5.4%). Postvoid residual (PVR) urine volume significantly increased with onabotulinumtoxinA versus placebo, with the highest volume at week 2 posttreatment, and 8.7% of patients had an increase from baseline of ≥200 mL in PVR urine volume at any time following the initial toxin treatment (none with placebo). The proportion of patients who initiated clean intermittent catheterization (CIC) at any time during treatment cycle 1 was 6.1% versus none in the placebo group; for over half the patients who initiated CIC (10/17), the duration of CIC was ≤6 weeks. This value is lower than those reported in previous studies on idiopathic DO [274–277,281]. In the study of Nitti et al. [278] discontinuation rates due to adverse effects were low both in the onabotulinumtoxinA (1.8%) and in the placebo (1.4%) groups.

DRUGS IN DEVELOPMENT

Among many potential targets for future treatment of LUTS/OAB [282], the most promising seems to be the purinergic [17,283] and cannabinoid [284,285] systems and the different members of the transient receptor potential (TRP) channel family [286,287]. P2X receptors are considered to be important in LUTS/OAB pathophysiology, and the use of $P2X_3$ receptor antagonists for treatment of these conditions has a good preclinical rationale, but clinical experiences are so far lacking. Clinical observations have indicated that different cannabinoid receptor agonists offer a promising therapeutic approach. In addition, inhibition of the degradation of endocannabinoids (inhibitors of fatty acid amide hydrolase) may be of therapeutic interest. Several members of the TRP channel superfamily, including TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1, are expressed in the bladder. They may act as sensors of stretch and/or chemical irritation. However, even if the TRPV1 agonists, capsaicin, and RTX have shown clinical efficacy [282], the roles of TRP channels for LUT function/dysfunction and their potential as therapeutic targets have not been established.

CONCLUSION

To effectively LUTS/OAB and to treat UI caused by DO, identification of suitable targets for pharmacological intervention is necessary. Such targets may be found in the CNS or peripherally. Since in most cases the causes underlying LUTS/DO are unknown, pharmacotherapy is mainly directed against symptoms. Several drugs alternatives are available, but none of them suitable for all patients. Since LUTS and OAB symptoms can have multifactorial pathophysiology, individually designed treatments are required for optimal effect, and combination therapy may be needed.

25 Uropathogens and the Lower Urinary Tract

Leslie Rickey

Urinary tract infections (UTIs) are a major cause of individual morbidity as well as societal cost. Between 40% and 60% of women will experience a UTI at some point during their lifetime [1]. According to the 2006 National Ambulatory Medical Care Survey and National Hospital Ambulatory Medical Care Survey, there are 8.1 million cases of UTIs a year in the United States and an estimated cost of 1.6 billion dollars annually [1,2]. Our understanding of the pathophysiology and bacterial factors related to UTIs has been greatly advanced over the last decade with the goal of identifying novel therapeutic targets and gaining better understanding of the host response. Researchers investigating the urinary microbiome have also begun to explore the relationship between the bacterial milieu of the bladder and lower urinary tract symptoms, which may represent an alternative treatment pathway for patients with overactive bladder symptoms. This chapter will review the current understanding of bacterial pathogenesis and host factors that play a role in UTIs as well as highlight relevant research developments regarding the urinary microbiome.

BACTERIAL PATHOGENESIS

Escherichia coli is the primary cause of community- and hospital-acquired UTIs [3] and has been the subject of the majority of uropathogen research. *E. coli* are generally referred to as intestinal or extraintestinal and can be either pathogenic or nonpathogenic depending on their genomic makeup that allows expression of certain virulence traits. There is a subset of extraintestinal *E. coli* associated with UTI, referred to as uropathogenic *E. coli* (UPEC). Current understanding implicates both bacterial and host factors that affect pathogenesis. Isolates from the urinary tract and rectal samples are often the same, suggesting that the intestinal tract is the primary source of UPEC [4]. Pathogenesis is conferred by virulence factors encoded in UPEC including adhesins that facilitate entry into urothelial cells, iron acquisition systems, and toxin secretion.

The first event that must occur in order for UPEC to colonize the lower urinary tract is attachment or binding to the urothelial cell. The presence of bacterial surface adherence factors called pili or fimbriae facilitates UPEC adhesion to host cells, and type 1 pili are common in *E. coli* isolates [5]. Interestingly, UPEC genomes can carry multiple gene clusters encoding for fimbria; therefore, similar strains of UPEC can have subpopulations with distinct pili, which increases the chances of adhesion [6]. Type 1 pili contain FimH subunits, an adhesin that is able to mediate urothelial cell invasion via uroplakin receptors on the urothelial cell surface [7]. In animal studies, a FimH-specific antibody was able to block urothelial adhesion and thus decrease bacterial counts in the urine [8]. Additionally, a FimH null mutant in a mouse UTI model resulted in decreased bacterial survival and decreased inflammatory response compared to *E. coli* expressing normal type 1 fimbria [9]. The Tamm–Horsfall protein (THP) is synthesized in the kidney and is an important host defense against the critical first step of bacterial adherence to the urothelium. THP binds to type 1-fimbriated *E. coli* and prevents bacterial adherence to the uroplakin receptors [10], and THP knockout mice are more prone to UTI. The THP-deficient mice carried higher bacterial loads and cleared bacteria more slowly than their wild-type counterparts [11].

Integrins are also surface adhesion molecules, and certain subtypes are bound by FimH. This attachment appears to facilitate bacterial uptake into host cells by communication with and reorganization of the actin cytoskeleton, a process that may be mediated by tyrosine kinase signaling pathways [12]. The bacteria then rapidly multiply within the superficial urothelial cells, and these infected cells are eventually exfoliated via an apoptosis-like pathway (Figure 25.1) [13]. While this mechanism allows the host to clear large numbers of bacteria, urothelial integrity is disrupted in the process. UPEC may in fact facilitate this response via proaptotic effects mediated by interactions with inflammatory cascade transcription factors such as NF-KB [14]. During exfoliation, some bacteria are released from the cell and are able to invade into deeper immature urothelial layers that are exposed during the exfoliation process [15,16]. At this stage, bacterial replication seems to be restricted by actin filaments [17] and thus these intracellular bacterial colonies (IBCs) confer a survival advantage by evading host defenses. In fact, it is thought that these quiescent bacterial communities may provide a reservoir for recurrent infections [15]. In addition, some bacteria take on a filamentous morphology and are able to avoid neutrophil phagocytosis [18], which provides a survival advantage and may contribute to sustained infection. In a mouse model, bacteria persisted in bladder tissue despite being cleared from the urine after gentamicin therapy [19], and although certain antibiotics reduced IBCs, UPEC reservoirs were not completely eradicated despite multiple antibiotic regimens [20].

Although it is known that bacterial invasion leads to epithelial cytokine production, the exact mechanism by which the inflammatory cascade is initiated is not well understood. The lipopolysaccharide (LPS) complex associated with the bacterial cell surface is recognized by CD14 and Toll-like receptors (TLR) on the urothelial cell surface, resulting in production of inflammatory mediators including interleukin-6 (IL-6) and IL-8, which in turn activates neutrophil recruitment to aid in bacterial clearance [21,22]. Polymorphisms in TLR can affect response to LPS; therefore, genetic variations may lead to alterations in host response to pathogens [23]. In the urinary tract, several TLR polymorphisms are associated with either increased susceptibility to or greater protection from UTI as well as number of UTI episodes [24]. There are several known toxins that modulate the host inflammatory response, induce cytopathic effects, and cause tissue damage. Alpha-hemolysin promotes cell lysis, appears to attenuate the host inflammatory response, and is associated with clinical severity [25,26]. Cytotoxic necrotizing factor 1 (CNF1) has been shown to cause membrane changes that facilitate bacterial internalization into host cells [27] and inhibit neutrophil activity in animal models [28].

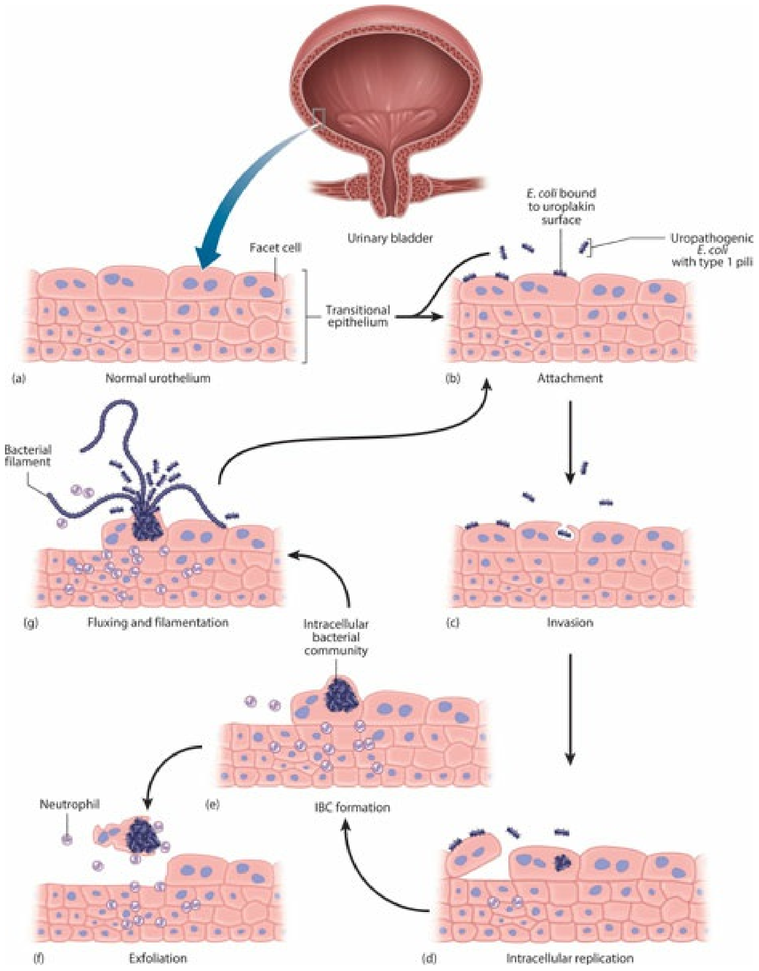

Figure 25.1 Uropathogenic *E. coli* (UPEC) intracellular bacterial colony (IBC) pathogenic pathway observed in the murine cystitis model. The bladder urothelium (a) is a pseudostratified transitional epithelium lined by large facet cells. These cells have an apical asymmetric unit membrane containing uroplakins that help form

the impermeable bladder barrier and also serve as receptors for UPEC. Bacteria introduced into the bladder adhere to the bladder surface via type 1 pili (b). Upon attachment, bacteria are able to invade (c) and replicate (d) within the facet cell cytoplasm. UPEC form large biofilm-like IBCs within these cells (e). Ultimately, the bacteria flux out of their intracellular niche (g), some adopting a filamentous morphology; they then adhere to other host cells and reenter the infectious cycle. During this process, infected urothelial cells are sloughed into the urine (f) and neutrophils are recruited to the site of infection. (Reproduced from Klumpp DJ et al., *Infect Immun*, 69, 6689, 2001.)

Iron is required for bacterial cellular processes and survival, and the competition for available iron stores highlights the impressive ability of UPEC to evade host defenses. One host defense is to limit iron availability via transferrin, an iron carrier protein that can move iron stores in and out of cells. However, UPEC can utilize enterobactin, which has a higher affinity for iron than transferrin and can therefore scavenge iron from the environment [29]. An additional host protein called lipocalin 2 specifically binds enterobactin and is upregulated in urothelial cells containing UPEC [30,31]; however, UPEC have yet additional iron acquisition systems that are not recognized by lipocalin and can therefore work around this host defense as well [32].

RELATIONSHIP OF BACTERIA AND LOWER URINARY TRACT SYMPTOMS

The relationship between bacteriuria and lower urinary tract symptoms has traditionally been restricted to symptoms related to UTIs. However, our understanding of “significant bacteriuria” has been challenged by recent advances in microbiology and more accurate descriptions of the type and number of bacteria present in the bladder.

The concept of significant bacteriuria defined as $>10^5$ CFU/mL was originally described by Kass in the 1950s [33] in an attempt to distinguish bacterial infection of the urinary tract from contamination as a risk factor for pyelonephritis. However, the effect of lower urinary tract bacteria on lower urinary tract symptoms is not likely isolated to what we currently term a “urinary tract infection.” It has been established that acute urinary tract symptoms can be associated with lower quantitative bacterial counts and that the presence of pyuria should be considered as well. Expert guidelines support that bacterial counts of $\geq 10^3$ CFU/mL associated with acute onset of dysuria should be considered a UTI as well [34,35]. In a study comparing young women with acute urinary symptoms were compared to asymptomatic controls, only 33% of the symptomatic women had bacterial counts $>10^5$; however, 70% had bacterial counts $>10^3$ (compared to 7% asymptomatic controls) [36]. In addition, when a cutoff of 20 leukocytes/mm^2 was used, pyuria was present in 77% of symptomatic women compared to 19.6% of controls. These results demonstrate not only the use of bacterial counts less than 10^5 when diagnosing a UTI in a symptomatic patient, but also the difficulty in establishing a clear cutoff that relates bacterial counts and pyuria to a true infection.

The significance of “low count bacteriuria” and how the urinary microbiome may contribute to LUTS is a topic of current investigation. When $\geq 10^4$ CFU/mL is used as a cutoff, bacteriuria is independently associated with nocturia (OR 3.21, CI: 1.02–10.14, $p = 0.046$), urgency (OR 7.02, CI: 1.49–33.05, $p = 0.01$), and bladder pain (OR 3.28, CI: 1.13–9.54, $p = 0.03$) in women without acute UTI symptoms [37]. Although the noninfected bladder has long been assumed to be a sterile environment, bacterial communities have been identified in a majority of culture-proven UTI-free female subjects using 16S rRNA gene sequencing [38]. Another group of investigators considered not only pyuria and urine culture, but also the presence of intracellular bacteria in epithelial cells shed in the urine. They found a significant difference in positive urine cultures in subjects with chronic LUTS compared to controls (17% vs. 2%, $p = 0.004$). Perhaps more striking, however, was the finding that 94% of symptomatic subjects had evidence of intracellular bacteria compared to 29% of controls ($p = 0.006$) [39], raising the possibility that cellular colonization may play a role in the development of LUTS. Interestingly, between-group differences in bacterial species were demonstrated in both urine culture and 16S rRNA ribotyping of intracellular bacteria. Finally difference in bacterial community have been shown in the urine of women [40]. The investigators also observed a decreased bacterial diversity in the urine from subjects vs. controls, which they note has been reported in the microbiota studies of chronic inflammatory states of the gastrointestinal tract as well.

In conclusion, advances in the science of bacterial pathogenesis as well as identification of host factors that may predispose an individual to colonization or altered immune response are increasing our understanding of the host–pathogen relationship in the urinary tract. Ongoing work in this area will not only allow clinicians to more accurately and effectively treat affected patients, but eventually inform preventative strategies for the millions of women suffering from UTI and other inflammatory disorders of the lower urinary tract.

26 Classification of Lower Urinary Tract Dysfunction in the Female Patient

David Staskin and Alan J. Wein

INTRODUCTION

Devising a Classification System

The purpose of a classification system is communication. The value of grouping and interrelating concepts and facts into an organizational structure can be measured by the ability of the final product to provide a logical framework for introducing new theories, scientific findings, and clinical observations into the existing knowledge. In addition, the system should act as a useful clinical tool for diagnosing and treating disease. Rather than create new areas of contention, a classification system that is proposed for general use should ideally incorporate ideas and resolve conflicts. The attempt to devise an all inclusive system that completely describes lower urinary tract (LUT) function and dysfunction and the decision to adopt this single classification system would certainly be ideal, but is confounded by difficulties in agreement concerning construct and the standardization of terminology.

Complex interrelationships create difficulty in maintaining the simplicity of such systems. Filling (storage) and voiding (emptying) dysfunction may be classified by multiple methods.

Classification can be done by symptoms (patient interview eliciting LUT symptoms), the precipitating LUT activity from those symptoms, and the anticipated condition as in Table 26.1; by bladder activity or outlet activity (overactive or underactive) as in Table 26.2; by neurological activity (neurogenic) as in Table 26.3; by objective LUT testing (urodynamic studies) as in Table 26.4; or descriptively in a more complex system that combines the aspects of structure (anatomy) function (physiology), disease states (clinical diagnosis and the expected effect on LUT function), and observed LUT behavior (LUT dysfunction associated with a specific lesion or disease) as in Table 26.5.

The standardization of terminology is vital to ensure that the meaning of a "common language" employed by the users of the system reflects the same symptoms and signs and methods and measurements. The reader is directed to the ICS Standardization of Terminology (Appendices I through V) for a review of ICS "standards" [1–5]. As with classification systems that must undergo constant evolution, the ICS terminology has been revised and terms have been added, modified, and even subtracted without substitution [6,7].

When devising and presenting these classification systems, ICS terminology has generally been preserved, but the reader will note some differences between the ICS terms and the utilization of descriptors in the expanded descriptive classification (e.g., "sensory" terminology) included in Table 26.5.

The following classification systems are oriented to LUT symptoms with or without incontinence. In the case of incontinence, the presumption is that the "wetness" experienced by the patient is urine and that the source of egress is the urethra.

The clinical assessment should rule out wetness secondary to perspiration, inflammation or discharge, or from vaginal and/or rectal sources. For example, specific to the differential diagnosis of "wetness" is the importance of ruling out vesicovaginal or ureterovaginal fistula. The extended descriptive classification attempts to provide a complex but illustrative functional model.

This chapter does not include an in-depth review of LUT pathophysiology, diagnosis, or therapy, but these are reviewed exhaustively elsewhere within this textbook. In addition, this chapter is not intended to be a review of the historical development of the various methods of classification, although prior historical models are selectively referenced. However, the readers are strongly encouraged to utilize these models to "organize their thoughts" and facilitate the development of a logical approach to care.

Proposing Simple and More Complex Classification Systems: Symptomatic and Functional

Classifications

A symptomatic classification system is presented in Table 26.1. It is based on the concept that symptoms may suggest inclusively the underlying abnormal activity, pathophysiology, and condition. Since the patient's symptoms may be extremely useful or misleading due to overlapping findings in LUT conditions [8–10], an illustrative differential diagnosis of common conditions is also presented.

A classification system that is specifically oriented toward the description of LUT function and activity should divide the LUT into its two anatomical areas—the "bladder" (detrusor) and "bladder outlet" (sphincter) during the physiological functions of "storage" (filling) and "emptying" (voiding). A simple functional classification is presented in Table 26.2. The bladder or outlet activity is described as "overactive," "normal," or "underactive." An overactive bladder (OAB) represents an unwanted increase in detrusor activity ("pressure," episode(s) of undesired contractility or a decrease in bladder compliance, or the "sensation of filing," an increase in afferent activity) during urinary storage; an underactive bladder represents insufficient detrusor activity/pressure during bladder emptying (absent or poorly sustained contraction). An overactive outlet describes increased activity or resistance/obstruction during emptying (anatomic blockage, deficient voluntary sphincter coordination, neurogenic sphincter dyssynergia), and an underactive outlet represents insufficient activity/resistance during storage (inadequate intrinsic function or altered anatomical support relationships). These abnormalities in function/activity can occur alone, or in combination [11–17].

Table 26.1 Classification by Symptoms

Stress urinary incontinence (SUI)
Symptom—The involuntary loss of urine on effort or exertion (lift, strain, cough, sneeze).
Activity—Underactive outlet.
Condition—Urodynamic stress incontinence: the involuntary loss of urine resulting from an increase in intra-abdominal pressure that overcomes the resistance of the bladder outlet in the absence of a true bladder contraction. The decrease in bladder outlet or urethral resistance may result from poor anatomical support of the bladder neck (urethral hypermobility/SUI-A) or a loss of urethral function (intrinsic sphincter deficiency SUI-ISD) or, most commonly, a mixture.
Clinical confusion—The patient describes the symptom of urinary loss with "activity" but the etiology of involuntary leakage is actually an uninhibited bladder contraction: SUI should have urinary loss synchronous with "effort"; similarly, many patients will describe SUI as a sensation, which is confused with "urgency"; finally, stress and urgency incontinence may coexist.

Urgency urinary incontinence (UUI)
Symptom—The loss of urine with the sensation of urgency, voiding before the ability to toilet.
Activity—Overactive bladder (OAB-wet): detrusor overactivity.
Condition—Urinary urgency incontinence (urodynamic): the involuntary loss of urine resulting from an increase in bladder pressure secondary to detrusor overactivity (an uninhibited bladder contraction or unstable bladder). Detrusor overactivity may be the result of a suprasacral spinal or intracranial neurological lesion that results in uncontrolled reflex contractions (detrusor hyperreflexia) or may be idiopathic. Patients may demonstrate other symptoms associated with "urgency" (frequency, urgency, nocturia) without urinary loss (OAB-dry).
Clinical confusion—The patient has decreased sensation and loses urine from motor activity of the detrusor without the feeling of "urgency." OAB is a syndrome consisting of the symptoms "urgency, with or without urgency incontinence, usually with frequency and nocturia" suggestive of urodynamic bladder overactivity but inclusive of "urgency and frequency without incontinence" OAB-dry (vida infra) or the sensation of urgency (desire to void in the absence of a detectable rise in detrusor pressure–sensory urgency).

Mixed urinary incontinence
Symptom—Mixed symptoms of UUI and SUI, urinary loss with effort and with urgency.
Activity—OAB-wet detrusor overactivity and underactive sphincter.
Condition—A mixture of the conditions described earlier as SUI and UUI.
Clinical confusion—Urinary loss may be from SUI or UUI but the predominance and bother resulting from one condition or the other may not be discernable from the history and physical exam alone, thus creating difficulty in choosing treatment for the "primary" symptom.

Urgency and frequency without incontinence
Symptom—Urgency and frequency without urinary loss.
Activity—Detrusor overactivity with compensatory sphincter activity or no detrusor activity or abnormal afferent activity or processing (sensory).
Condition—Urgency is the complaint of a sudden compelling desire to pass urine that is difficult to defer, and frequency is the complaint by the patient who considers that she voids too often by day or at night (going to bed and arising), whereas

nocturia is waking at night one or more times to void preceded by and followed by sleep. “Sensory urgency,” a term that has been removed from the ICS lexicon and was used to describe the sensation of urinary urgency without a detectable rise in detrusor pressure.

Clinical confusion—The classification of a moderate or strong “desire to void” without true “urgency” is unresolved. “Sensory urgency–desire to void” is not in the current ICS lexicon.

Overflow incontinence

Symptom—The involuntary loss of urine resulting from urinary retention with bladder overdistention. The retention (failure to empty) may result from inadequate bladder contractility or outlet obstruction (or both).

Activity—Underactive bladder (retention)/overactive outlet (obstruction).

Condition—Urinary loss occurs when the intravesical pressure overcomes the urethral resistance as a result of bladder contractility, increases in intra-abdominal pressure and/or urethral relaxation.

Clinical confusion—The symptoms that are described may be a mixture of stress (SUI) and urgency (OAB) complaints.

Altered bladder sensation and pain

Symptom—Frequent voiding with or without pain; conversely a loss of sensation.

Activity—No detrusor contraction/alteration in afferent input or processing.

Condition—Bladder pain, discomfort, and pressure can be characterized by type, frequency, duration, location, and precipitating and relieving factors. Bladder sensation can be described as increased, normal, reduced, absent, or nonspecific (neurologic). Increased or decreased voiding may be correlated with the sensation.

Clinical confusion—Urinary urgency and frequency without incontinence may be a product of abnormal sensation or bladder contractile activity. The source of pelvic pain may not be the lower urinary tract. Interstitial cystitis or chronic urethritis remain diagnoses of exclusion.

Functional incontinence

Symptom—The involuntary loss of urine resulting from a deficit in the ability to perform toileting functions secondary to physical or mental limitations.

Activity—Abnormal lower urinary tract function usually coexists with functional issues.

Clinical confusion—The underlying pathophysiology of stress, urge, or overflow incontinence may coexist, as well as difficulty in eliciting an accurate history. The patient’s primary “functional” issue may be dementia, delirium, or other forms of altered cognition; physical disability preventing easy and rapid toilet access. These conditions often exist alone or in combination with lower urinary tract dysfunction.

Table 26.2 Classification by Bladder and Outlet Activitya

Bladder	**Outlet**
Overactive (urgency)	Overactive (obstruction)
Normoactive	Normoactive
Underactive (retention)	Underactive (stress incontinence)

[a] Symptoms in parentheses.

The classification of neurogenic voiding dysfunction may also be adapted to a similar functional system based on the nature of the lesion and the expected behavior of the detrusor and sphincter and similarly can be correlated with symptoms as in Table 26.3 [18–23]. The neurological terms of detrusor hyperreflexia, normoreflexia, and areflexia and the outlet descriptive of dyssynergic, normal, or denervated are utilized and correlate with the type of function/activity.

The interrelationship between the LUT and the outlet, including the pelvic floor, requires a classification system that recognizes the individual contributions and the combined effects of the efferent systems (anatomy and function/activity), and the afferent systems from the bladder musculature and mucosa, the bladder neck, urethral mechanisms, and the pelvic floor structures [24–29]. It is simplistic to combine the effects of the bladder musculature and mucosa, the outlet/sphincter, and the levator complex on bladder activity without acknowledging the complex integration and interrelationship of these areas on LUT behavior. In addition, combining them into one functional area should not limit investigation into their individual contributions. The complex interrelationship of the bladder outlet and pelvic floor structures with voiding behavior are apparent in several common clinical conditions. For example, in the case of “urodynamic stress incontinence” or stress urinary incontinence (SUI), the ability to preserve or augment urethral basal tone, urethral sphincter function, and anatomical support from levator anatomy or contraction is critical for understanding the ability to maintain continence during “effort” [30–37]. Conversely, the initiation of voiding requires both pelvic floor and urethral sphincter relaxation in the absence of anatomical obstruction [23–28]. Conversely, symptoms of decreased emptying or urinary retention may result from the inhibition of detrusor contractility, secondary to increased pelvic floor or sphincter afferents, decreased afferent detrusor muscular or mucosal input, or voluntary contraction of the striated sphincter (psuedo-dyssynergia) during voiding. Similarly, an understanding of urgency incontinence and OAB syndrome symptoms require an appreciation of the relationship between afferent and efferent neurological pathways to the LUT, the bladder neck, and the pelvic floor on the detrusor, although definitive reflex arcs in the human may not have been identified [38–43].

Table 26.3 Classification by Neurological Activity

Neurogenic classification[a]			
Bladder/detrusor		Outlet/sphincter	
Hyperreflexic (overactive—urgency)		Uncoordinated (overactive—obstruction) Coordinated	
Normoreflexic		Denervated (underactive—stress inc.)	
Areflexic (underactive—retention)			
Expected behavior of the bladder, internal sphincter, and external sphincter based on location of the lesion			
	Bladder	Internal (smooth muscle) sphincter	External (skeletal) sphincter
Peripheral	Hypo-areflexic, underactive	Dernevated (+/−)	Denervated (+/−)
Infrasacral	Areflexic, underactive	Innervated	Denervated, underactive
Spinal	Hyperreflexic, overactive	Uncoordinated if T6 or above	Dyssynergic, overactive
Suprapontine	Hyperreflexic	Coordinated	Coordinated

EXPANDED CLASSIFICATION OF VOIDING DYSFUNCTION: INCLUDING PELVIC FLOOR ACTIVITY

Outlet Dysfunction: Bladder Outlet and Pelvic Floor

The underactive outlet: The bladder outlet (sphincteric mechanism) is responsible for "outlet resistance" during urinary storage. The bladder outlet remains closed at rest. Resistance to leakage is provided by the intrinsic closure pressure along the length of the urethra. The urethra can be divided into two functional areas: these are (1) the "proximal" sphincteric mechanism—a product of mucosa, submucosa, and smooth muscle incorporating the bladder neck and proximal urethra—and (2) the distal mechanism or "external" sphincteric mechanism located in the middle of the "anatomical urethra" and intimately related anatomically and physiologically to the levator ani complex. Anatomical support facilitates transmission of intra-abdominal pressure to both areas and is provided by both the anterior vaginal wall and its attachments to the pelvis, and by the constant tone (slow-twitch fibers). Active contraction (fast-twitch fibers) of the levator complex can increase this support, but is usually seen only after pelvic muscle training and is not a "normal" reflex.

SUI is the involuntary loss of urine per urethra—which occurs when intravesical pressure overcomes the urethral resistance owing to an increase in intra-abdominal pressure in the absence of a true bladder contraction. Urethral closure pressure is maintained by preserving or augmenting anatomical support and by increasing the intrinsic activity of the external sphincter complex. The preservation or enhancement of the anatomical backboard facilitates pressure transmission in the proximal and distal sphincteric mechanism and preserves the anatomical relationships of the sphincteric components to maintain or increase closure pressure. Proper anatomical support provides an obvious mechanical advantage and, just as importantly, allows efficient action of the individual structures. Type I or type II SUI is classified as "poor anatomical support," associated with bladder neck and urethral motion. However, an understanding of the contribution of pelvic floor activity and dysfunction allows one to appreciate that the etiology of urinary leakage is probably multifactorial. Classically, an important event in maintaining continence is the preservation of intra-abdominal pressure transmission to the bladder neck and proximal urethra with respect to the bladder during stress maneuvers. In addition, inhibiting the rotational motion of the urethra prevents a relative differential in the movement of the posterior urethra with relation to the anterior urethra and the development of a shearing force between the anterior and posterior urethral walls that decreases urethral coaptation and compression.

The most fixed point, and the area of maximal pressure transmission during increases in intra-abdominal pressure, is the external sphincter–levator complex in the midanatomical urethra. Transmission forces as well as active sphincteric contraction provide urethral resistance during stress maneuvers.

The combination of defects at many levels of the sphincteric mechanism may combine to decrease urethral resistance. Type III SUI, intrinsic sphincter deficiency or low urethral closure pressure, describes a deficiency in any of the intrinsic urethral functions through atrophy, denervation, devascularization, or scarring, as detailed earlier. The degree of pudendal nerve denervation during childbirth may contribute to deficiencies in anatomical support both by affecting levator support and by decreasing intrinsic sphincter function.

It is reasonable to assume that the complex etiology of SUI is a mixture of anatomical support abnormalities and intrinsic sphincter abnormalities. The pathophysiology is related to the relative loss of mechanical (ligament) support of functioning (innervated) intrinsic (urethral) and extrinsic musculature (slow- and fast-twitch fibers of the levator complex). Therapy may be directed at correcting the defect, or compensating for the deficiency, by increasing the function of another component that contributes to urethral resistance. In fact, the most common operation for SUI is a midurethral sling. The mechanism of action has been described as a "kinking" or "backboard" effect, which in fact does not correct the common finding of bladder neck hypermobility but does increase urethral resistance to leakage and compensates for defects in anatomical support and intrinsic urethral deficiency.

Table 26.5 Expanded Functional Classification of Voiding Dysfunction Including Bladder Afferents and Pelvic Floor Activity

I. Outlet dysfunction: bladder outlet and pelvic floor

A. Underactive outlet (decreased urethral resistance)

Symptomatic: SUI

1. Anatomical support defects (SUI-A) (types I and II SUI): pathophysiology—anatomical motion creates inequities in transmission pressures to bladder and outlet, overcoming urethral resistance, and/or and conformational changes caused by vaginal wall motion disrupt outlet integrity.
    - a. Anatomical defects of fascia, muscles, ligaments, and bony pelvis.
    - b. Functioning support: muscular contraction—denervation or the loss of identification, strength, or coordination of levator musculature.
    - c. A degree of ISD (see 2) that in combination with SUI-A I or II contributes to critical decreases in resistance during effort to permit urinary leakage.
2. ISD (SUI-ISD) (type III) (LUCP)
   Pathophysiology: deficiency of the urethral closure mechanism secondary to decreased innervation, vascularization or trauma to mucosa, submucosa, or smooth, nonstriated skeletal or skeletal musculature of the urethra—intrinsic deficiency of the closure mechanism.
    - a. Proximal urethral sphincter: bladder neck (smooth muscle) and proximal urethra (SUI-ISD-p).
    - b. External sphincter: denervation or loss of resting tone, voluntary or reflex contraction (SUI-ISD-d).
    - c. Combined or total proximal and external sphincter deficiency (SUI-ISD-t).
3. Combined SUI (SUI-A-ISD)
   Pathophysiology: a degree of both anatomical motion and sphincter dysfunction.
    - a. Leakage from ISD may exist without hypermobility.
    - b. Hypermobility alone without a degree of ISD is not sufficient to result in urinary loss.
4. Failure to inhibit the detrusor: decreased pelvic floor inhibitory activity of bladder (etiology for OAB—see C).
   Pathophysiology: failure to contract pelvic floor releases detrusor reflex and decreases ability to inhibit active contraction.
    - a. Neurological: (infrasacral) denervation (areflexia of pelvic floor).
    - b. Behavioral: failure to contract pelvic floor (lack of identification/strength/coordination).
    - c. Mechanical: damage to pelvic floor structures with intact innervation.

B. Overactive outlet (increased urethral resistance)

Symptomatic: overflow incontinence/retention; frequency–urgency.

1. Anatomical obstruction (physical blockage) Pathophysiology: increased outlet resistance secondary to compression or narrowing.
    - a. Iatrogenic: surgical (e.g., for urinary incontinence).
    - b. Other: congenital, inflammatory, neoplastic, traumatic.
2. Functional obstruction (failure of relaxation)
   Pathophysiology: increased outlet resistance—inappropriate contraction or failure of normal relaxation.
    - a. Neurogenic: detrusor sphincter dyssynergia (skeletal musculature).
    - b. Behavioral: failure to relax pelvic floor musculature or external sphincter.
3. Combined anatomical and functional obstruction
4. Inhibition of detrusor activity: increased pelvic floor activity
   Pathophysiology: failure to relax pelvic floor inhibits initiation of detrusor activity and inhibits ability to develop or continue a sustained detrusor contraction.
    - a. Neurological: (suprasacral) overactivity/hyperreflexia (dyssynergic pelvic floor activity).
    - b. Behavioral: failure to relax pelvic floor (learned, acquired, maladaptive, psychogenic).
    - c. Situational: “voluntary” inhibition secondary to environment or pain.

II. Bladder dysfunction

A. Detrusor overactivity (increased intravesical pressure)

Symptomatic: urgency incontinence (with or without sensation)—OAB-wet.

1. Involuntary detrusor contractions: detrusor overactivity (motor urgency). Pathophysiology: increased detrusor (intravesical) pressure overcomes urethral resistance or causes sensation of urinary urgency
    - a. Detrusor overactivity (DO): primary = idiopathic, subclinical neurological, or symptomatic phasic detrusor activity; secondary = obstruction, reflex urethral relaxation, increased detrusor/mucosal afferent activity. OAB-urgency, with (OAB-wet) or without (OAB-dry) incontinence, usually with frequency and nocturia (absence of other pathology).
    - b. Detrusor overactivity (hyperreflexia): suprapontine (intracranial) neurological lesion (with or without sphincter control); spinal (suprasacral) neurological lesion (with or without sphincteric dyssynergia).
2. Decreased compliance

Pathophysiology: increased intravesical pressure secondary to decreased accommodation of detrusor.
  a. Fibrosis: radiation, inflammation, immune response.
  b. Neurological: loss/reversal of accommodation reflex—conus medullaris or peripheral.
3. Combined detrusor contractions and decreased compliance
4. Pelvic floor underactivity (see I.A.4)—decreased pelvic floor inhibition

B. Underactive bladder (decreased intravesical pressure)
Symptomatic: overflow incontinence/retention
1. Peripheral denervation or neuropathy. Pathophysiology: decreased contractility—neural efferent or myogenic/decreased afferent stimulation.
  a. Congenital, inflammatory, neoplastic, or trauma lesion to peripheral nerves.
  b. Diabetes or other metabolic cause.
2. Detrusor myopathy
Pathophysiology: decreased contractility secondary to smooth muscle damage.
  a. Fibrosis/collagen deposition.
  b. Inflammation/obstruction/overdistension.
3. Pharmacological inhibition
Pathophysiology: decreased contractility secondary to receptor blockade of neural efferents or afferents.
  a. Antimuscarinics.
  b. Smooth muscle relaxants/spasmolytics/membrane stabilizers.
4. Pelvic floor overactivity (see I.B.4)

III. Combined outlet and bladder dysfunction (I and II)

IV. Disorders of sensation

A. Decreased sensation
1. Decreased bladder sensation. Pathophysiology: denervation, myopathy, behavioral, pharmacological.
  a. Decreased sense of fullness and normal urge response.
  b. Loss of sense of fullness/urge warning only with active contraction.
  c. Loss of sense of fullness/urge incontinence without appreciation of “desire to void.”
  d. Urinary retention without appreciation of distension.
2. Decreased bladder outlet and pelvic floor sensation
Pathophysiology: denervation, myopathy, behavioral, pharmacological causing decreased ability to identify/contract/coordinate.
  a. Bladder overactivity (I.A.4): failure to inhibit?
  b. Bladder underactivity (myogenic or mucosal) (II.B.4): failure to initiate?
  c. Contributory to decreased bladder sensation? (IV.A.1.a through d).
  d. Sexual dysfunction—anorgasmia.

B. Increased sensation
1. Increased sensation of the bladder/bladder outlet Pathophysiology: neuropathic, inflammatory, mucosal permeability defect, psychogenic, afferent amplification.
  a. Frequency–urgency symptoms.
  b. Suprapubic and pelvic pain syndromes.
2. Increased sensation of the pelvic floor/bladder outlet
Pathophysiology: neuromuscular myalgia, neuropathic, inflammatory, psychogenic.
  a. Levator myalgia.
  b. Frequency–urgency and pelvic pain syndromes.
3. Combined deficit

*Abbreviations:*LUCP, low urethral closure pressure; ISD, intrinsic sphincter deficiency; OAB, overactive bladder; Pelvic floor activity, in italics; SUI, stress urinary incontinence.

The overactive outlet: Failure to empty the bladder may be due to elevated outlet resistance or to impaired contractility of the bladder. The most commonly observed clinical etiology of elevated outlet resistance is iatrogenic, obstruction following incontinence surgery. Other forms of anatomic urethral obstruction are less common. Neurogenic outlet obstruction, commonly seen following injury to the suprasacral spinal cord, is due to a loss of coordination between the bladder and sphincter (detrusor sphincter dyssynergia). The paradoxical failure of the outlet to relax during voiding may result in anatomical obstruction to flow or to inhibition of the initiation or completion of the detrusor contraction. Contraction of the pelvic floor or sphincter is a normal response for bladder inhibition but, when pathological, may be classified as pseudodyssynergia (voluntary or behavioral) or true dyssynergia (neurogenic). The relaxation of the urethral sphincter during voiding and dyssynergic activity in spinal cord injury has been documented. It is not known whether the specific anatomical areas of the urethra or pelvic floor (sphincter urethra, compressor urethra, urethrovaginal sphincter, bulbocavernosus, anal sphincter, levator complex) act in unison, individually, or at all in detrusor inhibition in normal subjects.

The OAB: The symptoms of OAB syndrome are urgency, with or without urge incontinence, usually with frequency and nocturia. Multiple etiologies have been proposed including reduced suprapontine inhibition, damaged axonal paths in spinal cord, increased LUT afferent input, loss of peripheral inhibition, and enhancement of excitatory neurotransmission in the micturition reflex pathway. Therefore, the central and peripheral nervous systems mediate bladder control through complex voluntary pathways and reflex arcs. Central efferent control of the bladder smooth musculature is mediated by afferent activity from the detrusor musculature and bladder mucosa (facilitatory) and the reflex and voluntary contractions of the pelvic floor and sphincter musculature (inhibitory).

The underactive bladder: Traditional concepts of detrusor underactivity have focused on either efferent innervation or myogenic dysfunction. By contrast, contemporary views emphasize the importance of the neural control mechanisms, particularly the afferent system, which can fail to potentiate detrusor contraction, leading to premature termination of the voiding reflex. To void efficiently, a feedforward mechanism by which urinary flow in the urethra helps to enhance and maintain adequate contractile function of the bladder until the bladder is empty is required. Sensory information is fed back to the motor system at several levels of control between the end organ and brain cortex. These sensors themselves can be damaged, for example, through an effect of ageing or ischemia. In addition, impairment of innervation can lead to decreased information transfer via either the sensory or motor nerves. A functional disruption of higher central nervous regulatory systems can lead to functional abnormal voiding [44].

During the initial phase of bladder emptying, the pelvic floor and external sphincter relax in order to decrease urethral resistance and facilitate low pressure flow. In addition, this relaxation decreases the reflex inhibition of bladder contractility. Relaxation is followed by a detrusor contraction, which continues until voiding is completed. When emptying failure is secondary to bladder dysfunction, it may be a result of either detrusor smooth muscle pathology or insufficient neural stimulation of the detrusor. Insufficient neural stimulation may occur at the neuromuscular level (pharmacological), with nerve impairment (neuropathy), or with alterations in central control of micturition (conus medullaris, spinal column, or brain). The impairment of detrusor contractility by the absence of pelvic floor relaxation is evident in spinal cord disease (failure to empty following adequate sphincterotomy in the spinal cord patient due to incomplete detrusor contractions) and Parkinsonism (failure to empty secondary to pelvic floor bradykinesia).

Mixed–combined disorders: Disorders of the bladder and outlet during storage and emptying may occur alone and in combination. The most common in the female patient is underactive outlet (SUI) and OAB. In addition, the elderly females or patients with neurological diseases may demonstrate detrusor overactivity (hyperreflexia) with impaired contractility (poorly sustained contraction).

Sensory disorders: Afferent neurons from the bladder and urethra are of major importance during both the storage and emptying phases, both initiating the voiding reflex and sustaining the voiding drive during bladder emptying. Somatic activity may inhibit the emptying reflex by voluntary contraction of the external sphincter or pelvic floor—and although not established in humans, may provide inhibitory activity during bladder filling. Traditional classification systems have focused on motor rather than sensory activity. Disorders of bladder and bladder outlet sensation may result from central or peripheral denervation, from psychological causes, or from pharmacological agents such as pain medications. The role of decreased sensation in the function of the pelvic floor and the interaction between the pelvic floor and bladder with relation to the sensory pathway on the micturition reflexes await further investigation. The pudendal nerve is responsible for the innervation of pelvic floor structures as well as of the genital skin, urethral mucosa, and anal canal. Proprioceptive information of the periurethral musculature and sensory innervation of the levator ani muscles are also mediated by the pudendal branches. Increased sensation or pain attributed to the bladder is a major clinical challenge.

The symptoms of urinary frequency, urinary urgency, and suprapubic pressure often result in diagnostic evaluations and therapy for bladder disorders, even in the absence of definitive findings of mucosal or smooth muscle abnormality. Pain that may originate from fascial, muscular, or neurological etiologies within the pelvic floor should be included in the differential diagnosis of the patient with urethral or bladder syndromes.

Traditionally, sensory signaling in the urinary bladder has been largely attributed to direct activation of bladder afferents. There is substantive evidence that sensory systems can be influenced by nonneuronal cells, such as the urothelium, which are able to respond to various types of stimuli that can include physiological, psychological, and disease-related factors. The corresponding release of chemical mediators (through activation of a number of receptors/ion channels) can initiate signaling mechanisms between and within urothelial cells, as well as other cell types within the bladder wall including bladder nerves. However, the mechanisms underlying how various cell types in the bladder wall respond to normal filling and emptying and are challenged by a variety of stressors (physical and chemical) are still not well understood. Alterations or defects in signaling mechanisms are likely to contribute to the pathophysiology of bladder disease with symptoms including urinary urgency, increased voiding frequency, and pain [45].

In addition, pelvic floor or bladder pain and OAB should not be considered mutually exclusive in spite of the fact that each is usually exclusion criteria when studying the other during studies involving pharmacotherapy.

Summary: The classification of voiding dysfunction has been presented with the major focus incorporating the division of the LUT into the bladder and the bladder outlet and the “activity” during storage/filling and emptying/voiding. These systems can be clearly illustrated with the functional areas of the bladder and outlet on the vertical and axis the functions of filling/storage and voiding/emptying on the horizontal. These graphic representations can be utilized to correlate functional anatomy, LUT function, urodynamic testing, etiology, and therapy.

Classification systems will continue to evolve as our understanding of LUT functions expands and our understanding of the complex interactions of storage/filling and emptying, efferent/motor and afferent/sensory, bladder and outlet, LUT, and surrounding pelvic floor structures must assimilate this knowledge into the categorical constructs. The reader is encouraged to incorporate these systems into their own clinical algorithms and critique and modify them based on additional evidence or “opinion.”

27 Tissue Engineering and Regenerative Medicine for the Female Genitourinary System

Manish Patel and Anthony Atala

INTRODUCTION

Patients suffering from various congenital and acquired disorders of the reproductive tract are currently treated with surgical and hormonal therapies. These techniques are not ideal and do not routinely lead to physiological recovery of the affected organ or organs. This has led scientists in the field of regenerative medicine to apply the principles of cell transplantation, materials science, and bioengineering to construct biological substitutes that may eventually improve the quality of life for these patients.

The field of regenerative medicine encompasses various areas of technology such as tissue engineering and cloning. Tissue engineering combines the principles of cell transplantation, materials science, and bioengineering to develop new biological substitutes that may restore and maintain normal organ function. Tissue engineering strategies generally fall into two categories: the use of acellular matrices that allow the body's own regenerative systems and serve as scaffolds on which to direct new tissue growth and the use of matrices with cells. This chapter will discuss some of the principles of regenerative medicine as well as discuss some of the current research in the field of regenerative medicine for female genitourinary organs [1–4].

BIOMATERIALS IN TISSUE ENGINEERING

In many cell-based tissue engineering methods, cells are obtained from a tissue, expanded in vitro, and then seeded onto a scaffold composed of an appropriate biomaterial. These biomaterials replicate the biological and mechanical function of the native extracellular matrix (ECM) found in tissues in the body by serving as an artificial ECM. Biomaterials also provide a 3D scaffold for the cells to adhere forming new tissues with appropriate structure and function. They also allow for the delivery of cells and appropriate bioactive factors to desired sites in the body [5]. Bioactive factors, such as cell adhesion peptides and growth factors, can be seeded along with cells to help regulate and direct growth. Biomaterials can also provide mechanical support against in vivo forces and ensure that the predefined 3D structure of an organ is maintained during tissue development.

The ideal biomaterial should be biodegradable and bioresorbable to support the replacement of normal tissue without inducing inflammation. If the biomaterial is incompatible with the recipient, it may induce an inflammatory effect or immune response, which will lead to damage, necrosis, and cell death [6]. The biomaterial should also provide an environment in which appropriate regulation of cell behavior (adhesion, proliferation, migration, and differentiation) can occur so that functional tissue can form. Since biomaterials provide temporary mechanical support while the cells undergo spatial reorganization into tissue, the properly chosen biomaterial should allow the engineered tissue to maintain sufficient mechanical integrity to support itself in early development, while in late development, it should begin to degrade so that it does not hinder further tissue growth [5].

Three broad classes of biomaterials have been utilized in tissue engineering studies: naturally derived materials (e.g., collagen and alginate), acellular tissue matrices (e.g., bladder submucosa [BSM] and small intestinal submucosa [SIS]), and synthetic polymers such as polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA). Collagen is the most abundant and ubiquitous structural protein in the body and may be readily purified from both animal and human tissues with an enzyme treatment and salt/acid extraction. Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues. The matrices are often prepared by mechanical and chemical manipulation of a segment of tissue [1–4]. These matrices slowly degrade upon implantation and are replaced and remodeled by new ECM proteins synthesized and secreted by transplanted or ingrowing host cells. Commonly used acellular tissue matrices include BSM and SIS.

Polyesters of naturally occurring a-hydroxy acids, including PGA, PLA, and PLGA, are also widely used in tissue engineering. These polymers have gained FDA approval for human use in a variety of applications, including sutures. Because these polymers are thermoplastics, they can be easily formed into a 3D scaffold with a desired microstructure, gross shape, and dimension [7]. Other biodegradable synthetic polymers, including poly(anhydrides) and poly(ortho esters), can also be used to fabricate scaffolds for tissue engineering with controlled properties [8].

CELLS FOR TISSUE ENGINEERING

Human Embryonic Stem Cells

Human embryonic stem cells (hESCs) exhibit two remarkable properties: the ability to proliferate in an undifferentiated but pluripotent state (self-renewal) and the ability to differentiate into almost all of the specialized cell types in the body [9]. These cells are isolated by aspirating the inner cell mass from the embryo during the blastocyst stage (5 days after fertilization). hESCs have been shown to differentiate into cells from all three embryonic germ layers in vitro. Skin and neurons have been demonstrated, indicating ectodermal differentiation [10–13]. Blood, cardiac cells, cartilage, endothelial cells, and muscle have also been shown, indicating mesodermal differentiation [14–16]. Pancreatic cells have been formed, indicating endodermal differentiation [17]. The tendency, however, to form teratomas in vivo is a limitation to widespread usage of hESCs in cell therapy and tissue engineering as it is difficult if not impossible to control the tumorigenicity of these cells in vivo leading to a number of safety concerns surrounding the usage of these cells for therapeutic benefit. In addition, the ethical considerations surrounding the destruction of human embryos to obtain hESCs are yet to be resolved. Finally, the use of hESCs is banned in some countries, including the United States, and so their use in tissue engineering is infrequent in those countries at this time.

Laboratory-Generated Stem Cells

In addition to hESCs, stem cells for tissue engineering can be generated through “cloning” procedures. Somatic cell nuclear transfer (SCNT) is used to generate early-stage embryos that are explanted in culture to produce embryonic stem cell lines whose genetic material is identical to that of its source. These autologous stem cells have the potential to become almost any type of cell in the adult body and thus would be useful in tissue and organ replacement applications [18]. Therefore, SCNT may provide an alternative source of transplantable cells. There are, however, a number of limitations that require further study before this technique can be applied widely in tissue or organ replacement therapy. First, the efficiency of the cloning process is very low as evidenced by the fact that the majority of embryos derived from the cloning process do not survive [19–21]. In addition, cell cycle synchronization between donor cells and recipient oocytes must be accomplished [22]. Other barriers to the frequent use of SCNT in human applications are the requirement for human oocytes, which are difficult to obtain in the quantities required, and, as with hESCs, there are ethical considerations surrounding the production and destruction of human embryonic tissue that remain to be resolved.

Transformation of adult cells into pluripotent stem cells through a type of genetic “reprogramming” has also been described. Reprogramming is a technique that involves dedifferentiation of adult somatic cells to produce patient-specific pluripotent stem cells, without the use of embryos. Cells generated by reprogramming would be genetically identical to the somatic cells (and thus the patient who donated these cells) and would not be rejected. Takahashi and Yamanaka [23] were the first to discover that mouse embryonic fibroblasts and adult mouse fibroblasts could be reprogrammed into an “induced pluripotent state” (iPS). The resultant iPS cells possessed the immortal growth characteristics of self-renewing embryonic stem cells, expressed genes specific for ES cells, and generated embryoid bodies in vitro and teratomas in vivo. When iPS cells were injected into mouse blastocysts, they contributed to a variety of cell types. However, although iPS cells selected in this way were pluripotent, they were not identical to ES cells. Unlike ES cells, chimeras made from iPS cells did not result in full-term pregnancies. The epigenetic state of the iPS cells was found to be somewhere between that found in somatic cells and that found in ES cells, suggesting that the reprogramming was incomplete.

These results were improved significantly by Wernig et al. [24]. They observed that the number of reprogrammed colonies increased when drug selection was initiated later (day 20 rather than day 3 posttransduction). This suggests that reprogramming is a slow and gradual process and may explain why previous attempts resulted in incomplete reprogramming. Takahashi et al. [25] showed that retrovirus-mediated transfection of OCT3/4, SOX2, KLF4, and c-Myc generates human iPS cells that are similar to hES cells in terms of morphology, proliferation, gene expression, surface markers, and teratoma formation. Yu et al. [26] showed that retroviral transduction of OCT4, SOX2, NANOG, and LIN28 could generate pluripotent stem cells without introducing any oncogenes (c-MYC). Both studies showed that human iPS were similar but not identical to hES cells.

Another concern is that these iPS cells contain three to six retroviral integrations (one for each factor) that may increase the risk of tumorigenesis. Okita et al. [27] studied the tumor formation in chimeric mice generated from Nanog iPS cells and found 20% of the offspring developed tumors due to the retroviral expression of c-Myc. An alternative approach would be to use a transient expression method, such as adenovirus-mediated system, since both Okita et al. and Meissner et al. [28] showed strong silencing of the viral-controlled transcripts in iPS cells. This indicates that these viral genes are only required for the induction, not the maintenance, of pluripotency.

Amniotic Fluid Stem Cells

An alternate source of stem cells is from amniotic fluid. Amniotic fluid is known to contain multiple partially differentiated cell types derived from the developing fetus. Stem cell populations were isolated from these sources, called amniotic fluid stem cells (AFSCs), that express embryonic and adult stem cell markers [29]. The undifferentiated stem cells expand extensively without a feeder layer, and the population doubles every 36 hours. Lines were maintained for over 250 population doublings retaining long telomeres and a normal karyotype. The AFS cells are broadly multipotent. Clonal human lines verified by retroviral marking can be induced to differentiate into cell types representing each embryonic germ layer, including cells of adipogenic, osteogenic, myogenic, endothelial, neuronal, and hepatic lineages. In this respect, they meet a commonly accepted criterion for pluripotent stem cells, without implying that they can generate every adult tissue. However, unlike hESCs, AFSCs do not form tumors in vivo, which would be advantageous in clinical applications. The cells could be obtained either from amniocentesis or chorionic villous sampling in the developing fetus or from the placenta at the time of birth. The cells could be preserved for self-use, could be used without rejection, or could be banked.

Adult Stem Cells and Native Progenitor Cells

One of the limitations of applying cell-based regenerative medicine techniques to organ replacement has been the inherent difficulty of growing specific cell types in large quantities. Even when some organs such as the liver have a high regenerative capacity in vivo, cell growth and expansion in vitro may be difficult. By studying the privileged sites for committed precursor cells in specific organs as well as exploring the conditions that promote differentiation, one may be able to overcome the factors that limit cell expansion in vitro. For example, though urothelial cells could be grown in the laboratory setting, these types of cultures had only limited expansion capability. Several protocols have been developed over the past two decades that have overcome this difficulty. Studies have identified the undifferentiated cells in a urothelial culture, and culture techniques to keep them undifferentiated during their growth phase have been developed [30–32]. Using these cell culture methods, it is now possible to expand a urothelial strain from a single specimen that initially covers a surface area of 1 cm^2 to one covering a surface area of 3202 m^2 (the equivalent of one football field) within 8 weeks [30]. These studies have indicated that it should be possible to collect autologous bladder cells from human patients, expand them in culture, and return them to the donor in sufficient quantities for reconstructive purposes. In fact, expanded urothelial cells have been used in several clinical studies, including an important study that showed that a tissue-engineered bladder could be implanted into select patients [33]. Major advances have been achieved within the past decade on the possible expansion of a variety of primary human cells, with specific techniques that make the use of autologous cells possible for clinical application.

TISSUE ENGINEERING OF SPECIFIC ORGANS OF THE GENITOURINARY TRACT

Lower Urinary Tract

Bladder

Regenerative medicine with selective cell transplantation may provide a means to create functional new bladder segments. The success of cell transplantation strategies for bladder reconstruction depends on the ability to use donor tissue efficiently and to provide the right conditions for long-term survival, differentiation, and growth. Various cell sources have been explored for bladder regeneration. Native cells are currently preferable due to their autologous source, wherein they can be used without rejection [30]. It has been shown experimentally that the bladder neck and trigone area has a higher propensity of urothelial progenitor cells [34], and these cells are localized in the basal region [35]. Amniotic fluid– and bone marrow–derived stem cells can also be used in an autologous manner and have the potential to differentiate into bladder muscle [36] and urothelium [37]. ES cells as described earlier also have the potential to differentiate into bladder tissue [38].

Human urothelial and muscle cells can be expanded in vitro, seeded onto polymer scaffolds, and allowed to attach and form sheets of cells. The cell–polymer scaffold can then be implanted in vivo. Histological analysis indicated that viable cells were able to self-assemble back into their respective tissue types and would retain their native phenotype [39]. It has been well established for decades that portions of the bladder are able to regenerate generously over free grafts, most likely because the urothelium is associated with a high reparative capacity [40]. However, bladder muscle tissue is less likely to regenerate in a normal fashion. Both urothelial and muscle ingrowth are believed to be initiated at the edges of the injury, from the normal bladder tissue in toward the region of the free graft. Usually, however, contracture or resorption of the graft has been evident. Inflammation in response to the matrix may contribute to the resorption of the free graft (Figures 27.1 and 27.2).

As a result of this discovery, it was hypothesized that building the 3D bladder constructs in vitro, before implantation, would facilitate the eventual terminal differentiation of the cells after in vivo implantation. Further, this could minimize the inflammatory response, thus avoiding graft contracture and shrinkage. In a dog model [2], matrices that were seeded with cells and then used for bladder augmentation retained most of their preimplantation diameter, as opposed to matrices implanted without cells, in which significant graft contraction and shrinkage occurred. In addition, histological analysis demonstrated a marked paucity of muscle cells and a more aggressive inflammatory reaction in the matrices implanted without cells. The results of these initial studies showed that the creation of artificial bladders may be achieved in vivo; however, it could not be determined whether the functional parameters noted were created by the augmented segment or by the remaining native bladder tissue.

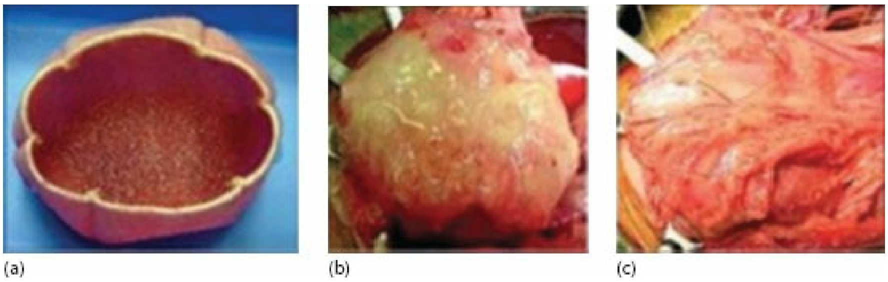

Figure 27.1 Scaffold seeded with cells (a) and engineered bladder anastomosed to native bladder with running 4-0 polyglycolic sutures (b). Implant covered with fibrin glue and omentum (c). (From Atala A et al., *Lancet*, 367(9518), 1241, April 15, 2006. With permission.)

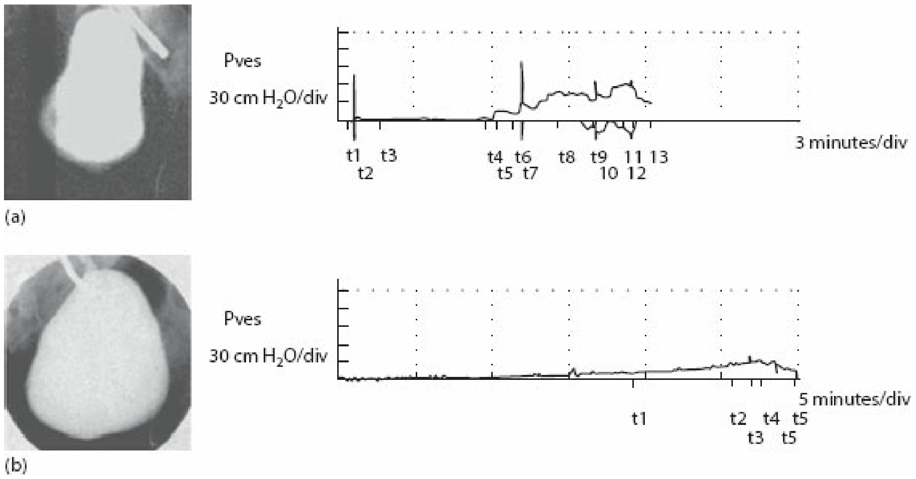

Figure 27.2 Preoperative (a) and 10-month postoperative (b) cystograms and urodynamic findings in a patient *i*th collagen–polyglycolic acid scaffold engineered bladder. (From Atala A et al., *Lancet*, 367(9518), 1241, April 15, 2006. With permission.)

Not all scaffold materials perform well if a large portion of the bladder must be replaced. In a study using SIS for subtotal bladder replacement in dogs, both the unseeded and cell-seeded experimental groups showed graft shrinkage and poor results [41]. This confirms that the type of scaffold used in the construction of tissue-engineered bladders is critical for the success of these technologies. The use of bioreactors, which provide mechanical stimulation for the growing organ in vitro, has also been proposed as an important parameter for success [42]. Bioreactors provide mechanical stimulation such as periodic stretching of the tissue, which has been shown to assist in in vitro muscle development, and exposure to flow conditions, which is important for the development of endothelial layers in blood vessels and hollow organs such as the bladder. In fact, Farhat and Yeger [42] have developed bioreactor systems specifically for bladder development. These systems provide simulated filling/emptying functions to the engineered tissue, and this may lead to a bladder construct with more functionality. A clinical experience involving engineered bladder tissue for cystoplasty was conducted starting in 1998. A small pilot study of seven patients reported the use of either collagen scaffolds seeded with cells or a combined PGA–collagen scaffold seeded with cells for bladder replacement. These engineered tissues were implanted with or without omental coverage. Patients reconstructed with engineered bladder tissue created with cell-seeded PGA–collagen scaffolds and omental coverage showed increased compliance, decreased end-filling pressures, increased capacities, and longer dry periods over time [33].

Although the experience to date is promising and shows that engineered tissues can be implanted safely, it is just a first step toward the goal of engineering fully functional bladders. Only a limited clinical experience exists to date, and the technology is not yet ready for wide dissemination, as further experimental and clinical studies are required.

Urethra

Various strategies have been proposed over the years for the regeneration of urethral tissue. Woven meshes of PGA without cells [43,44] or with cells [45] were used to regenerate urethras in various animal models. Naturally derived collagen-based materials such as decellularized BSM [4] and acellular urethral submucosa [46] have also been tested in various animal models for urethral reconstruction. The BSM matrix [4] proved to be a suitable graft for repair of urethral defects in rabbits. The grafts demonstrated a normal urothelial luminal lining and organized muscle bundles on the outer portion of the graft. These results were confirmed clinically in a series of men with a history of failed hypospadias reconstruction. The urethral defects in these patients were repaired with human bladder acellular collagen matrices [47]. The neourethral tissue was created by anastomosing the matrix to the urethral plate in an onlay fashion. The size of the created neourethra ranged from 5 to 15 cm. After a 3-year follow-up, three of the four patients had a successful outcome in regard to cosmetic appearance and function. One patient who had a 15 cm neourethra created developed a subglandular fistula (Figure 27.3).

Similar results were obtained in pediatric and adult patients with primary urethral stricture disease using the same collagen matrices [48]. Another study in 30 patients with recurrent stricture disease showed that a healthy urethral bed (two or fewer prior urethral surgeries) was needed for successful urethral reconstruction using the acellular collagen-based grafts [49]. More than 200 pediatric and adult patients with urethral disease have been successfully treated in an onlay manner with a bladder-derived collagen-based matrix. One advantage of this matrix over the traditional nongenital tissue grafts that have been used for urethroplasty is that the matrix material is “off the shelf.” This eliminates the necessity of additional surgical procedures for graft harvesting, which may decrease operative time as well as the potential morbidity due to the harvest procedure.

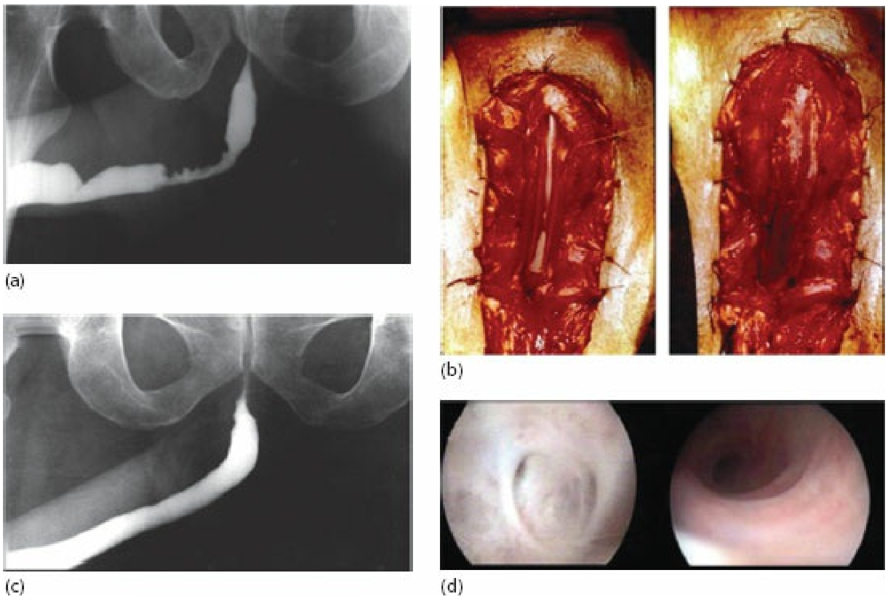

Figure 27.3 Representative case of bulbar stricture. Preoperative urethrogram (a). Urethral repair (b). Strictured tissue is excised, preserving the urethral plate on left side and matrix is anastomosed to urethral plate in an onlay fashion on right side. Urethrogram 6 months after repair (c). Cystoscopic view of urethra preoperatively on left side and 4 months after repair on right side (d). (From El-Kassaby AW et al., *J Urol*, 169(1), 170, January 2003. With permission.)

These techniques, which employed acellular matrices that had not been reseeded with cells, were applied experimentally and clinically in a successful manner for onlay urethral repairs. However, further study indicated that when tubularized urethral repairs with unseeded matrices were attempted experimentally, adequate urethral tissue regeneration was not achieved, and complications such as graft contracture and stricture formation occurred [50]. To determine if seeding the matrix with cells from the urinary tract could improve the results of tubularized urethral repairs, autologous rabbit bladder epithelial and smooth muscle cells were grown and seeded onto preconfigured tubular matrices. Entire urethral segments were then resected and urethroplasties were performed with tubularized collagen matrices either seeded with cells or without cells. The tubularized collagen matrices seeded with autologous cells formed new tissue that was histologically similar to native urethra. The tubularized collagen matrices without cells lead to poor tissue development, fibrosis, and stricture formation. These findings were confirmed clinically when a trial using tubularized nonseeded SIS for urethral stricture repair was performed in eight evaluable patients. Two patients with short inflammatory strictures maintained urethral patency. Stricture recurrence developed in the other six patients within 3 months of surgery [51].

Female Reproductive Organs

Uterus

Congenital malformations of the uterus may have profound implications clinically. Patients with cloacal exstrophy or intersex disorders may not have sufficient uterine tissue present for future reproduction. In addition, acquired causes including hysterectomy due to malignant or benign diseases or due to uterine adhesions are clinically important as the effect approximately 3%–5% of the population. For this group of patients, the only option of having genetic offspring is gestational surrogacy. The possibility of engineering functional uterine tissue using autologous cells has been investigated. Campbell et al. [52] performed a study in which the peritoneal cavity of rats and rabbits were used as in vivo bioreactors to produce uterine tissue grafts. In this study, biomaterial templates of the appropriate shape were implanted in the peritoneal cavities of rats or rabbits. After 2–3 weeks, the templates were removed, and the encapsulating myofibroblast-rich tissue that resulted from the foreign body response to the biomaterial was harvested. This tissue was then used to replace resected segments of the uterus in the same animals in which the tissue was grown. They reported that at 12 weeks after grafting, this novel uterine graft tissue thickened and developed the morphology of normal uterus. This structure included a lumen lined with endometrium, which was surrounded by several layers of smooth muscle cells (myometrium-like) interspersed with collagen. Importantly, these grafted uterine horns supported embryos to the late stages of gestation.

In another study by Li et al. [53], a collagen-targeting basic fibroblast growth factor (bFGF) delivery system was constructed. This bFGF delivery system was tested in a rat model of severe uterine damage. In this model, partial uterine horn excision was performed, and then the excised horn was reconstructed using the collagen-based delivery system. This study showed improved regeneration of both the endometrium and muscular cells, improved vascularization, and better pregnancy outcomes in the rats reconstructed with the system.

Uterine Cervix

The dysfunctional uterine cervix may also benefit from tissue engineering strategies. Spontaneous preterm birth is a frequent complication of pregnancy, and in some cases, abnormalities of the cervix have been implicated in this issue. House et al. [54] have shown that tissue engineering techniques can be used to create 3D cervical-like tissue constructs. Cervical cells were isolated from two premenopausal women and seeded on porous silk scaffolds. These constructs were cultured under dynamic or static culture conditions. After an 8-week culture interval, cervical cells had proliferated in all three dimensions and had synthesized an ECM with biochemical constituents and morphology similar to native tissue, but this matrix was better formed under dynamic culture conditions. This study suggested that it may be possible to engineer cervical tissue for a variety of conditions.

Vagina

Similarly, several pathological conditions, including congenital malformations like Mayer–Rokitansky–Kuster–Hauser (MRKH) syndrome, cloaca or thick transverse vaginal septum, obstetric trauma, and malignancy, can adversely affect normal vaginal development or anatomy. Vaginal reconstruction has traditionally been challenging due to the paucity of available native tissue. The feasibility of engineering vaginal tissue in vivo has been investigated [55]. Vaginal epithelial and smooth muscle cells of female rabbits were harvested, grown, and expanded in culture. These cells were seeded onto biodegradable polymer scaffolds, and the cell-seeded constructs were then implanted into nude mice for up to 6 weeks. Immunocytochemical, histological, and Western blot analyses confirmed the presence of vaginal tissue phenotypes. Electrical field stimulation studies in the tissue-engineered constructs showed similar functional properties to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement, patent vaginal structures were noted in the tissue-engineered specimens, while the non-cell-seeded structures were noted to be stenotic [55]. The first case of creation of a human vagina using autologous in vitro cultured vaginal tissue has also been reported [56]. The patient had MRKH syndrome and tissue was grown from a 1 cm^2 biopsy of vaginal vestibular mucosa. Autologous reconstructed vaginal tissue reached 314 cm^2 in 2 weeks. A McIndoe–Reed–type procedure was then performed to create a vaginal space to allow inlay of cultured tissue. Clinical exam demonstrated a vaginal vestibular mucosa with normal length and depth with normal vaginal tissue on biopsy [57] (Figures 27.4 and 27.5).

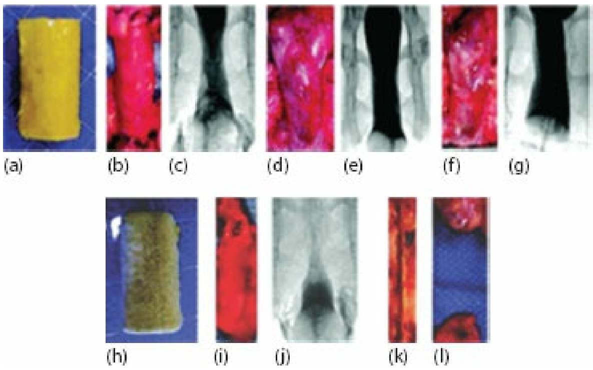

Figure 27.4 Appearance of tissue-engineered neovaginas. (a) Tubular polymer scaffold after cell seeding and 1-week in vitro culture, before implantation in vivo. (b, d, f) Gross appearance and (c, e, g) vaginography of cell-seeded constructs 1, 3, and 6 months, postimplantation, respectively. (h) Unseeded control scaffold before implantation. (i, k, l) Gross appearance of unseeded construct at 1, 3, and 6 months postimplantation. (j) Vaginography of unseeded graft at 1 month. (From De Filippo RE et al., *Transplantation*, 86(2), 208, July 27, 2008. With permission.)

Ovary

The fundamental role of the ovary is to produce oocytes capable of fertilization as well as to secrete hormones that will prepare the uterus for successful implantation. Ovarian sex steroids also play a major role in breast development, bone health, and sexual function in the female. A number of pathological conditions such as premature ovarian failure and cancer chemotherapy may severely compromise reproductive function. In addition, with the decline of sex steroid hormones around natural menopause, significant pathology, such as vasomotor symptoms, genital atrophy, and bone loss, ensues. In the attempt to restore a functional ovary, several approaches have been employed at the experimental level. Some of the significant approaches include regenerating ovarian tissues from stem cells, transplanting ovarian tissues, and use of tissue engineering tools.

Regenerating Ovarian Tissues from Stem Cells

It was previously considered that the germ cell renewal (formation of oocyte and follicle) is restricted to fetal life. A decade ago, Johnson et al. [60], during their investigation of follicular atresia in adult mouse, identified a group of cells in the ovarian surface epithelium immunostained positive for germ cell–specific marker, mouse vasa homologue, and showed BrdU (5-bromodeoxyuridine) incorporation. These germ-line stem cells (GSCs) were reported to maintain the oocyte and follicle production in the postnatal ovary. Even though there existed a debate on the existence of these stem cells in adult mammalian ovaries and their potential significance, a report by Zou et al. [61] provided concrete evidence that they are capable of producing offspring. The existence of these GSCs in an adult mammalian (mouse) ovary was reported to be exceedingly rare (0.014%) [62], and they seemed to decline with age [63]. As an alternative, extraovarian stem cells such as bone marrow–derived stem cells [64], ES, and iPS have been used to produce oocyte-like cells [63]. The differentiating ES were reported to have various limitations including their heterogeneity, which makes the in vitro oogenesis from these stem cells challenging.

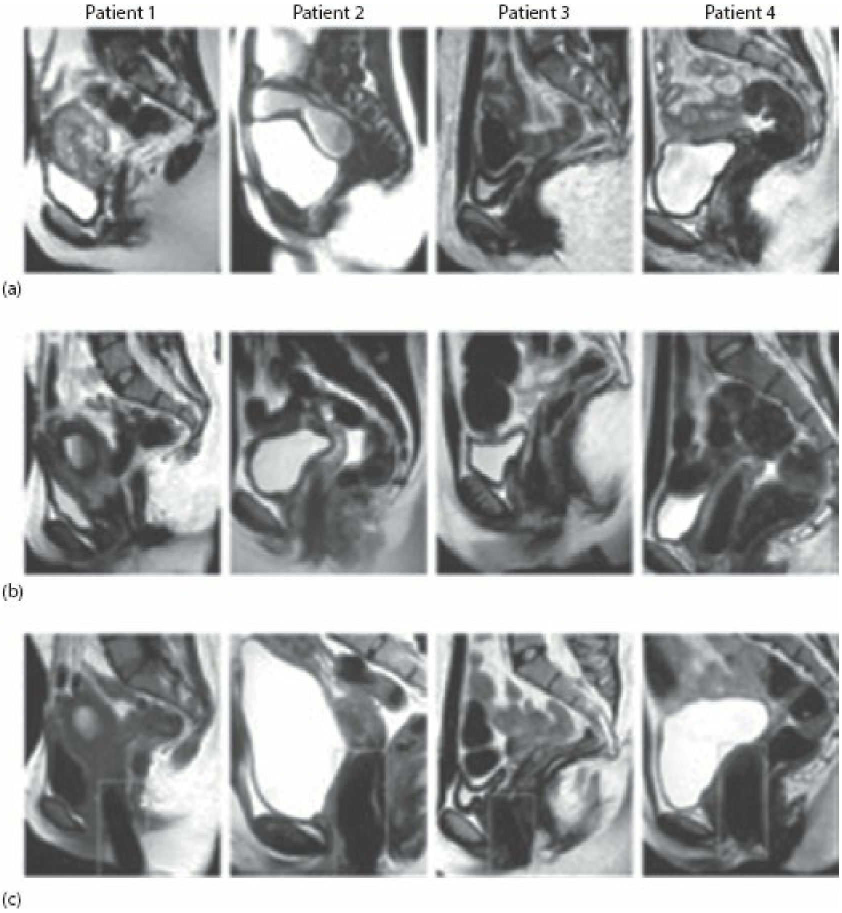

Figure 27.5 Preoperative and postoperative MRI images. Preoperative MRI images show absence of vaginal organs (a). MRIs 1 year after surgery show engineered vaginal organs (b). Latest MRI images up to 8 years after surgery (c) (boxes within the MRIs show engineered vaginal organs). (From Raya-Rivera AM et al., *Lancet*, 384(9940), 329, July 26, 2014. With permission.)

Autologous Transplantation of Ovarian Tissues after Cryopreservation or In Vitro Activation

Cryopreservation of ovarian tissues retrieved from both donors and autologous sources is another feasible approach to restore lost ovarian function. Autologous transplantations of cryopreserved whole ovary or partial ovarian tissues into rabbits [65], sheep [66,67], and monkeys [68] were reported to exhibit functions of the ovary including follicle development, resumption of regular cycles, and ovulation with corresponding hormone patterns. Kawamura et al. [69] reported a promising technique for autologous transplantation that recapitulates the fertility in a murine ovarian failure model, where follicular growth was induced through disruption of the Hippo signaling. When it comes to heterologous (allogenic or xenogenic) transplantation, the graft tissue has to be protected from the host immune system either by immune suppression or by immunoisolation. As discussed later, the use of tissue engineering tools is considered as a viable approach to overcome the immune hurdles. Since the functional unit of the ovary (follicle) is comprised of three major cells types, namely, oocyte, granulosa, and theca cells, and are extremely interdependent on each other for function, it has been a challenge to come up with a tissue design to accommodate all these cells in the same construct.

Tissue Engineering Approaches in Ovarian Biology

Recently, new in vitro culture methods involving tissue-engineered matrices have been developed to study the maturation of ovarian follicles [70,71]. The 2D culture systems support the production of immature mouse follicles or granulosa cell–oocyte complexes where the granulosa cell is attached to the culture substrate and migrates away from the oocyte [72]. In contrast, Shikanov et al. [73] have developed hydrogels to mimic the native ovarian environment by maintaining the 3D follicular architecture, cell–cell interactions, and paracrine signaling that direct follicular development. In this system, fibrin and alginate are gelled simultaneously and make up an interpenetrating network (FA-IPN). The degradable component of this FA-IPN may be particularly critical for clinical translation in order to support the greater than millionfold increase in volume that human follicles normally undergo in vivo. Krotz et al. [74] developed a design that they claimed as prefabricated self-assembled artificial human ovary. In this design, theca cells were cultured to form a honeycomb structure using agarose molds and later cumulus–oophorus complexes (COCs) were seeded in the luminae (multiple openings of the honeycomb structure). After 72 hours, theca cells surrounded the COCs and formed self-assembled complex microtissues reported to support the development of the oocyte, which was evident from the polar body extrusion. These kinds of artificial ovarian tissues serve as useful tools for in vitro maturation. On the other hand, for the purpose of cell-based hormone replacement therapy, Sittadjody et al. [75] have developed an engineered multilayer ovarian tissue model that secretes sex steroids and peptide hormones in response to gonadotropins in vitro. Theca and granulosa cells placed in different layers of multilayer alginate microcapsules that mimic the architecture of native follicles, their endocrine functions were found to be more potent than two other possible combinations. Similarly, encapsulated endocrine cells implanted into the peritoneum of rodents have been reported to deliver hormones in ovariectomized animals [76].

CONCLUSION

Regenerative medicine technologies for virtually every type of tissue and organ are currently being developed. Various tissues are at different stages of development. Some tissues have been used clinically such as bladder, urethral, and vaginal tissue, while others are still in preclinical development. The recent explosion in research in this field suggests that engineered tissues will likely represent a viable therapeutic option for patients in the future.

Section IV

Diagnostic Evaluation of Incontinence and Urogenital Prolapse

28 History and Examination

Vik Khullar and Rhiannon Bray

INTRODUCTION

A precise history and examination are integral to the management of women with bladder or pelvic floor dysfunction. An accurate history is required to determine a woman's symptoms; a thorough examination ascertains the woman's signs. While this chapter deals with salient aspects of history and examination, it should be remembered that this information alone is not sufficient in the assessment of a woman. Other tools are employed to supplement the information obtained from taking a history and examining a woman. These include bladder diary and questionnaires to determine the impact of symptoms on her quality of life, expectations, and goals.

The most recent standardization document produced jointly by the International Continence Society (ICS) and International Urogynecology Association (IUGA) defines symptoms as any morbid phenomenon or departure from the normal in structure, function, or sensation experienced by the woman and indicative of disease or a health problem [1]. Symptoms are either volunteered by or elicited from the individual or may be described by the individual's caregiver. The environment, the activities of daily living, and a woman's ability to cope with her disease can profoundly alter her quality of life. A woman who is always close to a toilet may not notice her urinary frequency, but the same woman with no access to a toilet may have urinary incontinence, wear protective pads, and be severely incapacitated.

Can the severity of urinary symptoms be modified by behavior? Lifestyle changes are first-line treatments in the management of women with lower urinary tract symptoms (LUTS). Reduction of fluid intake improves symptoms of urgency and frequency [2]. Women with severe detrusor overactivity may restrict their fluid intake to less than 200 mL per day. On direct questioning, the urinary problem may not appear severe, with a normal diurnal urinary frequency, and it is only with a frequency/volume chart that a complete picture of the severity of symptoms can be determined. The volume of urine excreted relies not only on fluid intake but also on the secretion of antidiuretic hormone, which is impaired in diabetes insipidus. The circadian secretion of this hormone may be affected in women suffering nocturia and nocturnal polyuria [3].

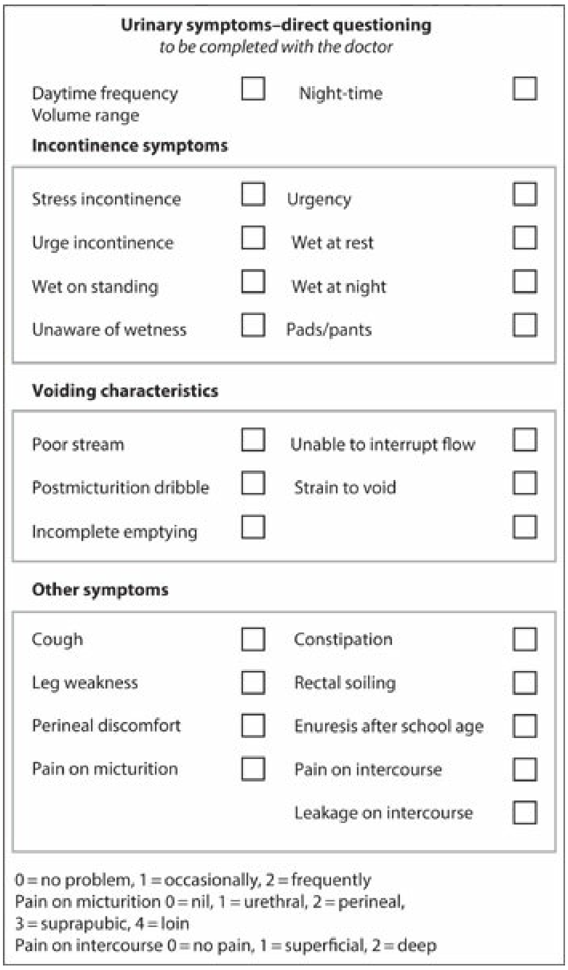
The most recently published ICS/IUGA standardization report on lower urinary tract terminology was published in 2010 [1], and the definitions used in this chapter are according to the terminology used in the report. The use of standardized terminology during the taking of the history is essential as it ensures accurate characterization of symptoms.

History

History taking must take place using the woman's own words. Women often fail to understand terms such as stress incontinence with a majority thinking that this relates to being mentally stressed and then leaking [4]. Therefore, symptomatic women may misclassify their urgency incontinence as stress incontinence due to this misunderstanding. This is then clarified into an easily understandable list of graded symptoms using a standard questionnaire (Figure 28.1). In a large study of women in five countries, the overall prevalence of urinary incontinence was 13.1%, with stress urinary incontinence the most common subtype (6.4%), followed by mixed urinary incontinence (2.4%) and urgency incontinence (1.5%) [5]. Across all countries surveyed, this trend is consistent. In another large cross-sectional web-based survey of over 15,000 women, the prevalence of stress urinary incontinence at least "sometimes" was found to be as high as 31.8% and urgency incontinence 24.4% [6]. Current data describe a wide variation in prevalence rates of incontinence in women, but the latest International Consultation on Incontinence reports that 10% of all adult women report leakage at least weekly and 25%–45% experience occasional leakage [7]. In general, the prevalence of all types of incontinence increases with age.

When comparing the symptoms and final urodynamic diagnosis, there is a marked overlap between diagnostic groups. A diagnosis based on history corresponds to urodynamic diagnosis in only up to 55% of women [8]. However, the use of a self-completed symptom questionnaire does produce a better relationship between urinary symptoms and urodynamic diagnosis [9]. Symptom complexes have been used in an attempt to improve diagnostic accuracy. The use of a bladder diary to enable patients to record fluid intake, output, and incontinence episodes for at least 24 hours can be extremely helpful in the initial assessment of urinary incontinence. It may also be therapeutic as it provides insight into bladder behavior, and it can be utilized to monitor the effectiveness of treatment during follow-up.

If symptoms are not of diagnostic value, why record them? Symptoms are valuable as a guide in determining treatment. In addition, symptoms should be taken into consideration during the urodynamic test as the provocative maneuvers should mimic conditions encountered by the woman in her normal daily activities and lead to her urinary symptoms. A 90-year-old woman with urgency and no stress incontinence is an inappropriate candidate for performing “star jumps” with a full bladder!



Urinary symptoms–direct questioning
to be completed with the doctor

Daytime frequency ☐
Volume range
Night-time ☐

Incontinence symptoms

Stress incontinence ☐
Urge incontinence ☐
Wet on standing ☐
Unaware of wetness ☐
Urgency ☐
Wet at rest ☐
Wet at night ☐
Pads/pants ☐

Voiding characteristics

Poor stream ☐
Postmicturition dribble ☐
Incomplete emptying ☐
Unable to interrupt flow ☐
Strain to void ☐
☐

Other symptoms

Cough ☐
Leg weakness ☐
Perineal discomfort ☐
Pain on micturition ☐
Constipation ☐
Rectal soiling ☐
Enuresis after school age ☐
Pain on intercourse ☐
Leakage on intercourse ☐

0 = no problem, 1 = occasionally, 2 = frequently
Pain on micturition 0 = nil, 1 = urethral, 2 = perineal,
3 = suprapubic, 4 = loin
Pain on intercourse 0 = no pain, 1 = superficial, 2 = deep

Figure 28.1 Standard questionnaire for urinary symptoms.

When questioning women complaining of urinary symptoms, all symptoms complained of should be explained in a woman’s own words. Stress incontinence is the term used to describe the symptom of urinary leakage that occurs with effort or exertion or on coughing or sneezing.

The severity of each symptom and its effect on the woman’s quality of life are noted, as improvement can be achieved through directing treatment to relieve the troublesome symptoms. The length of time that the symptoms have been present discriminates between transient and established incontinence and whether this has changed over time. General enquiry should be made of all urinary symptoms as the woman may not be able to describe them or may be too embarrassed to mention them. For this reason, a questionnaire is a useful guide as it ensures that all symptoms are enquired about.

The questionnaire should be validated in the language in which it is to be used and often the symptom questionnaire will be attached to a quality-of-life questionnaire [10,11]. The method used to obtain the symptoms will alter the answers. Questionnaires postally administered appear to produce higher severity responses from patients than the same questions used in an interview; this is particularly the case with questions of an embarrassing nature such as those relating to incontinence with sexual activity [12].

Table 28.1 Classification of Symptoms into Groups

- Abnormal storage
  - Incontinence: urge, stress
  - Frequency/nocturia
  - Nocturnal enuresis
- Abnormal voiding
  - Straining to void
  - Hesitancy
  - Incomplete emptying
  - Poor stream
  - Postmicturition dribble
- Abnormal sensation
  - Urgency
  - Dysuria
  - Absent sensation
  - Painful bladder

Symptoms can be grouped into storage LUTS, voiding LUTS, or postmicturition LUTS (Table 28.1). However, this classification of symptoms does not help in diagnosis as the same symptom can be produced by different mechanisms. For example, overflow incontinence can produce symptoms similar to those of detrusor overactivity: urinary frequency in overflow incontinence is caused by incomplete bladder emptying resulting in a reduced bladder capacity, whereas detrusor overactivity causes urinary frequency due to an overactive detrusor.

URINARY SYMPTOMS

Urinary Incontinence

Urinary incontinence is a failure of urinary storage and requires careful evaluation; it is defined as the complaint of any involuntary loss of urine [1]. It is important that incontinence is regarded as a symptom or a sign and not a diagnosis. Severe urinary incontinence of any origin has overlapping symptoms associated with urethral sphincter incompetence and detrusor overactivity. There are many causes of urinary incontinence (Table 28.2). It is important to determine whether the urine loss is continuous or intermittent.

Continuous urine loss is rare. It is usually seen when there is an ectopic ureter or fistula, and the woman will often complain of nocturnal incontinence as opposed to nocturnal enuresis. This occurs most often following pelvic surgery or as a result of malignancy or radiotherapy. Obstetric fistulae are more commonly seen in developing countries. Some women complain that they are “never dry” and suffer from severe intermittent urinary incontinence rather than a continuous loss of urine. This occurs in women who have had multiple previous operations and have a fixed and fibrosed “drainpipe” (type 3) urethra [13]. Otherwise, women who complain of urinary loss “all the time” have severe detrusor overactivity.

Table 28.2 Causes of Urinary Incontinence

- Urethral sphincter incompetence
  - Sphincter dysfunction
  - Abnormal bladder neck support
- Detrusor overactivity
  - Idiopathic detrusor overactivity
  - Neurogenic detrusor overactivity (e.g., multiple sclerosis, spinal trauma)

- Mixed incontinence
- Urethral diverticula
- Congenital abnormalities (e.g., epispadias, ectopic ureter, bladder exstrophy, spina bifida occulta)
- Transient incontinence
  - Urinary tract infection
  - Restricted mobility
  - Constipation
  - Excessive urine production
    - Diuretic therapy
    - Diabetes mellitus
    - Diabetes insipidus
    - Cardiac failure
    - Hypercalcemia
  - Confusion (e.g., dementia, acute illness)
  - Atrophic urethritis and vaginitis
- Pharmacological causes (e.g., diuretics, tranquilizers, cholinergic agents, prazosin)
- Fistulae (e.g., urethral, vesical, ureteral)
- Overflow incontinence
  - Hypotonic detrusor
  - Rarely urethral obstruction
- Urethral instability
- Functional

The pattern of intermittent urinary incontinence should be linked with associated activity such as physical exercise, laughing, putting the key in the front door, sexual intercourse, or orgasm. The severity of the incontinence can be quantified not only by volume but also by the type and number of pads or changes of underwear required in 24 hours and the magnitude of the provoking stimulus. There is often little relationship between the findings of urodynamic tests and the symptoms described by the woman in her daily life, and this may reflect modifications in behavior and lifestyle that she has made to ameliorate the effect of lower urinary tract dysfunction. It does not, however, reduce the importance of the urinary symptoms as they may still be impairing her quality of life. Often, women will not admit to urinary incontinence but state that they leak when a history is taken.

Urgency and Urgency Incontinence

Urgency is the sudden compelling desire to pass urine that is difficult to defer [1]. Urgency incontinence is the involuntary leakage of urine that is accompanied or immediately preceded by urgency [1]. Often, women will describe getting the sensation of the desire to void and not getting to the toilet in time. The quantity of urine lost can be anything from a few drops on lowering the undergarments prior to voiding to quite a large volume, and it is not uncommon for the patient to describe at least one occasion where the urine has poured down both legs uncontrollably.

This may be triggered by changes in temperature, opening the front door, hearing running water, and occasionally during sexual intercourse or orgasm. As the main coping strategy for this symptom is increasing voiding frequency, pad usage or incontinent episodes are not useful in assessing the severity of the condition.

The overactive bladder syndrome is defined as urgency, usually accompanied by increased daytime frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology [1].

Increased Daytime Frequency

Daytime frequency is the number of times a woman voids during waking hours; normal diurnal frequency is considered to be between four to seven voids per day. In a symptomatic population, the range may be greater. Increased daytime frequency is defined as the complaint by the patient that she voids more frequently during waking hours then previously deemed normal by the woman [1]. Accordingly, this is a subjective definition dependent on each individual rather than a numerical cutoff. Increased daytime frequency is not diagnostic for detrusor overactivity or for urodynamic stress incontinence although women with detrusor overactivity do void more frequently overall. Clustering of voids during the day may suggest a cause such as diuretics prescribed for congestive cardiac failure, drinking large volumes of fluid, or bad habit. Increased daytime urinary frequency may occur for a number of reasons (Table 28.3). The diurnal frequency does not increase with age in the symptomatic population seen in a urodynamic clinic (Table 28.4). The 95% upper limit of normal for urinary frequency in an asymptomatic population has been reported as being 13 voids per day, and this suggests a wide variation in the normal population as the median and mean values in this test–retest study was eight and seven, respectively [14].

Nocturia

Nocturia is defined as the complaint that the patient has to wake one or more times during the night to void; each void is preceded and followed by sleep [1]. It is important to discriminate between nocturia and a woman voiding because she is awake. It is difficult to be precise about the prevalence of nocturia, but approximately 50% of adults report waking once at night and 24% waking twice [5]. Waking twice or more has been associated decreased quality of life and increased bother [15]. Nocturia can be extremely disruptive and affect quality of life as well as being associated with other comorbidities such as hip fractures in the elderly [16]. The normal upper limit to the number of voids alters with age. If a woman passes urine more than once a night up to the age of 70 years, this is abnormal; voiding at night increases on average once every decade after the age of 70 in normal women (Table 28.5). This change is probably due to changing sleep patterns in the elderly. There may also be an effect of comorbidity—for example, postural effects resulting from daytime pooling of extracellular fluid in the lower limbs returning to the vascular compartment at night, as a result of subclinical heart failure.

Table 28.3 Causes of Abnormal Urinary Frequency

- Increased fluid intake and urine output; normal bladder capacity
  - Osmotic diuresis (e.g., diabetes mellitus).
  - Abnormal antidiuretic hormone production (e.g., diabetes insipidus).
  - Polydipsia; often the woman enjoys drinking a favorite beverage and only rarely is the behavior psychotic.
- Reduced functional bladder capacity
  - Inflamed bladder, increasing bladder sensation (e.g., acute bacterial cystitis, interstitial cystitis)
  - Detrusor overactivity
  - Habit or fear of urinary incontinence
  - Urinary residual secondary to detrusor hypotonia or outlet obstruction (rare)
  - Increased bladder sensation, normal bladder (e.g., anxiety)
- Reduced structural bladder capacity
  - Fibrosis after infection (e.g., tuberculosis)
  - Noninfective cystitis (e.g., interstitial cystitis, carcinoma)
  - Irradiation fibrosis (e.g., for bladder or cervical carcinoma)
  - Postsurgery (e.g., partial cystectomy)
  - Detrusor hypertrophy
- Decreased urinary frequency
  - Detrusor hypotonia
  - Impaired bladder sensation (e.g., diabetic neuropathy)
  - Reduced fluid intake

Table 28.4 Diurnal Frequency in a Symptomatic Populationa

Age (years)	**Mean frequency**	***n***
5–14	6.00	5
15–24	4.48	41
25–34	5.47	176
35–44	6.31	364
45–54	6.05	513
55–64	5.87	361
65–74	5.63	263
75–84	5.04	137
85–94	5.93	33

Total: 1893

[a] Patients seen in the urodynamic clinic, King’s College Hospital, London, between January 1993 and September 1994.

Table 28.5 Nocturnal Voids and Nocturia with Agea

Age (years)	**Mean voids per night**	**Nocturia (%)**	***n***
5.14	0.8	0	5
15–24	1.24	17	41
25–34	1.79	27	176
35–44	1.83	38	364
45–54	1.53	30	513
55–64	1.94	31	361
65–74	2.2	47	263
75–84	2.55	46	137
85–94	2.69	58	33

[a] Patients seen in the urodynamic clinic, King’s College Hospital, London, between January 1993 and September 1994.

It is important to discriminate between the woman who is awake and therefore voids and the woman who is woken by the desire to void; the first group of women often have no increase in their diurnal urinary frequency.

Nocturnal Enuresis

Nocturnal enuresis is the complaint of involuntary loss of urine occurring during sleep. It is important to differentiate between this complaint and waking with urgency and then leaking before arriving at the toilet, which is urgency urinary incontinence.

Nocturnal enuresis can be primary or secondary. Primary nocturnal enuresis starts in childhood and can persist into adulthood, the woman never having consistently been dry at night. Secondary nocturnal enuresis is when the incontinence restarts in adulthood following a period of nighttime continence, even if it resolved as a child.

The causes of nocturnal enuresis can be abnormal circadian secretion of antidiuretic hormone, detrusor overactivity or abnormal control of the micturition reflex, or abnormal sleep pattern. A family history should be sought and the presence of diurnal symptoms noted.

Nocturnal Urine Volume

This is defined as the total volume of urine passed between the time the individual goes to bed with the intention of sleeping and the time of waking with the intention of rising. Therefore, it excludes the last void before going to bed but includes the first void after rising in the morning.

Nocturnal Polyuria

Nocturnal polyuria is present when an increased proportion of the 24 hour output occurs at night (normally during the 8 hours while the patient is in bed). The normal range of nocturnal urine production differs with age and normal ranges have not been defined. Generally, nocturnal polyuria is present when more than 20% (young adults) to 33% (greater than 65 years) is produced at night.

Stress Urinary Incontinence

Stress urinary incontinence is defined as the involuntary loss of urine with exertion or effort or with coughing and sneezing. It is associated with activities involving a rise in intra-abdominal pressure without associated urgency and must be differentiated from urgency urinary incontinence when obtaining a history. The accuracy of diagnosing urodynamic stress incontinence based on the pure symptom of stress urinary incontinence (even with a normal frequency/volume chart) is poor, with 8% of incontinence in this group being due to detrusor overactivity or other causes [17].

Mixed Urinary Incontinence

Women with mixed urinary incontinence satisfy the definitions for having both stress urinary incontinence and urgency urinary incontinence. The prevalence of mixed urinary incontinence is variable but can account for approximately 40% of Western women who present with symptoms of urinary incontinence [18]. It is important to determine the balance between the two symptoms, ascertaining that one bothers her more as this can guide initial management. Women with mixed urinary incontinence are a challenge to manage and have an associated worse outcome after continence surgery than women with pure stress urinary incontinence [19].

Postural Urinary Incontinence

This is a new definition produced by the joint report of IUGA/ICS [1]. It defines postural incontinence as the complaint of the loss of urine associated with change of body position, for example, rising from a seated or lying position.

Coital Incontinence

The latest definition of coital incontinence produced by the joint report of IUGA/ICS describes coital incontinence as the complaint of involuntary loss of urine associated with coitus that may be further subdivided into incontinence with penetration or with orgasm. Urinary leakage on penetration is more likely to occur in women with urethral sphincter incompetence and with a cystocele. This type of urinary incontinence is not associated with urgency. Urinary incontinence can also occur with orgasm. The leakage may be associated with urgency and is thought to be related to detrusor overactivity [20].

Insensible Incontinence

Insensible incontinence is the occurrence of urinary leakage where the woman is unaware of how it occurred. Women may describe discovering urine in their underwear or on a pad that they wear at the end of the day because of the involuntary leakage of which they were unaware.

VOIDING SYMPTOMS

Voiding difficulties may present with a variety of symptoms. Voiding symptoms are symptoms experienced during the voiding phase [1].

Hesitancy

Hesitancy is defined as the description by an individual of having difficulty in initiating micturition [1] resulting in a delay of the onset of voiding after she is ready to pass urine. It is not common in women but when described the volume voided on these occasions should be noted as attempting to void with only a small volume in the bladder can be difficult even where bladder function is normal. However, hesitancy when voiding with a full bladder may be an indication that (1) the urethral sphincter is not relaxing when the detrusor contracts (voiding dysfunction or there is neurological disease, detrusor sphincter dyssynergia), (2) the detrusor muscle is not contracting effectively during voiding, or (3) psychological inhibition of bladder contraction, which might be considered in women who report only being able to void when alone. This symptom of hesitancy does not discriminate between these potential causes. Women with increased daytime frequency may complain of hesitancy and poor stream but this probably relates to the small volumes of urine passed.

Straining to Void

Straining to void describes the muscular effort used to initiate, maintain, or improve the urinary stream [1]. The intra-abdominal pressure is increased during a Valsalva maneuver, which increases the intravesical pressure and this can improve the instantaneous flow rate. The urinary stream is impaired overall and may be intermittent, each transient increase in flow associated with an increase in intra-abdominal pressure. In the longer term, this method of voiding can lead to the development of urogenital prolapse.

Incomplete Emptying

The feeling of incomplete emptying is a self-explanatory term for a feeling experienced by the individual after passing urine [1]. The sensation can be due to the fluid remaining in the bladder and can be secondary to an abnormality of sensation or due to after contractions in women with detrusor overactivity. Women in the latter group rarely have increased postmicturition urinary residual volumes.

Women with prolapse can develop a functional obstruction of the urethra due to external compression and may have urinary residuals. A cystocele can act as a sump and a rectocele can press anteriorly on the urethra in women who void by straining, preventing complete emptying. Urinary retention is now defined as the inability to pass urine despite persistent effort. This may be also caused by urinary tract infection, the presence of an intra-abdominal mass such as fibroid uterus or gravid uterus, or a consequence of neurological compromise such as women who suffer stroke, spinal cord injury, or multiple sclerosis.

Postmicturition Dribble

Postmicturition dribble is the term used when an individual describes the involuntary loss of urine immediately after she has finished passing urine [1], usually after leaving the toilet in men or after rising from the toilet in women. This symptom may be related to a urethral diverticulum, a cystourethrocele, or detrusor overactivity. Where detrusor contractions occur after the completion of voiding, urgency will often accompany the urinary leakage. Postmicturition dribble should be distinguished from terminal dribble, which is the term used when an individual describes a prolonged final part of micturition when the flow has slowed to a trickle or dribble [1].

Slow Stream

Slow stream is reported by the individual as a perception of reduced urine flow [1], usually compared to previous performance or in comparison to others. Decreased urinary stream is often described as “decreased force.” Urine flow rate is dependent on the volume of urine passed; if it is less than 150 mL, this should be assessed with reference to a frequency/volume chart. A reduced urine flow can be due to voided volumes below 150 mL, bladder outflow obstruction (2% of women), or decreased bladder contractility. Detrusor sphincter dyssynergia can produce intermittent flow that can be due to a neuropathic cause where the urethral sphincter does not relax during voiding or a myopathic cause.

Position-Dependent Micturition

This new definition describes the complaint of having to adopt specific positions to be able to micturate spontaneously or improve bladder emptying. Women may describe squatting, sitting forward on the toilet, or leaning backward in order to void.

Bladder/Urethral Pain

Pain, discomfort, and pressure are part of a spectrum of abnormal sensations felt by the individual. Pain produces the greatest impact on the patient and may be related to bladder filling or voiding, may be felt after micturition, or be continuous. Pain should also be characterized by type, frequency, duration, and precipitating and relieving factors and by location such as bladder, urethral, vulval, vaginal, and perineal pain. Dysuria, strangury, and bladder spasm are not recommended terms as these symptoms are difficult to define.

Urethral Pain

This is felt in the urethra and the individual indicates the urethra as the site [1]. It is often described as “burning on passing urine” and can be aggravated by sexual intercourse. As an isolated symptom, it is associated with urinary tract infections or urethritis.

Bladder Pain

Bladder pain is felt suprapubically or retropubically and usually increases with bladder filling [1]; it may also persist after voiding. Bladder pain may be associated with inflammation of the bladder, bladder stones, or tumor. Some women complain of pain after voiding, which might be associated with detrusor overactivity.

The presence of bladder pain is an indication for cystoscopy and occasionally bladder biopsy.

Suprapubic pain may also be associated with the pathology outside the bladder but within the pelvis and thus would be called pelvic pain. Endometriosis on the bladder may cause urethral pain, which is present at certain times in the menstrual cycle. Pelvic inflammatory disease may cause urethral pain; however, the woman will often have symptoms of vaginal discharge and pyrexia.

Table 28.6 Causes of Loin Pain

Vesicoureteric reflux
Renal trauma
Acute ureteric obstruction Stone Blood clot Papillary necrosis
Chronic ureteric obstruction Tumor (e.g., transitional cell carcinoma, renal cell carcinoma, Wilms' tumor) Ureteric stricture Retroperitoneal fibrosis Stone Congenital anomaly
Renal inflammation Pyelonephritis Perinephric abscess
Renal infarction

Loin Pain

This pain originates in the flank and radiates to the groin of the ipsilateral side. The pain is referred from the sensory nerves innervating the kidney and ureter, for which there are many causes (Table 28.6). Acute or chronic obstruction of the urinary tract can cause pain. This becomes more acute as the pressure generated within the urinary tract is higher. Loin pain during voiding and loin pain associated with urgency in women with detrusor overactivity may indicate vesicoureteric reflux.

Dyspareunia

This is the symptom of pain during sexual intercourse. This can be subdivided into superficial and deep dyspareunia. Superficial dyspareunia may be associated with vaginal dryness or following episiotomy or vaginal wall repair. Dyspareunia associated with compression of the anterior vaginal wall may reflect bladder or urethral pain syndromes. Perineal pain is felt between the posterior fourchette and the anus and may be persistent or recurrent episodic. It may be related to the micturition cycle or associated with symptoms suggestive of urinary tract or sexual dysfunction [1].

Prolapse Symptoms

Pelvic organ prolapse often coexists with and may contribute to LUTS. Women may describe the feeling of a lump, heaviness, a dragging sensation in the vagina, or lower back pain. They may also describe the learned behavior of using their fingers to reduce the bulge in order to successfully micturate or defecate, which is referred to as digitation. As vaginal prolapse alters the range of treatments for urinary incontinence, enquiries about symptoms of vaginal prolapse and prolapse affecting micturition and defecation should be made. The feeling of a lump at or beyond the vaginal introitus, low back ache, heaviness, dragging sensation, or the need to digitally replace or support the prolapse in order to defecate or micturate are among the symptoms that may be described. Over 40% of women with urethral sphincter incompetence will also have significant cystoceles, making this an important symptom affecting management of a woman's urinary incontinence. As vaginal prolapse can mask urethral sphincter incompetence (occult incontinence) it is important to identify any prolapse before a urodynamic test so that a vaginal ring can be inserted during the filling phase of urodynamics to expose any underlying urethral incompetence (21).

Hematuria

Visible blood in the urine (“frank hematuria”) should always be investigated as a priority, according to national guidelines. Microscopic hematuria should also be investigated, but trace amounts of blood on dipstick urinalysis can probably be disregarded.

GYNECOLOGICAL SYMPTOMS

It is important to enquire about changes in urinary symptoms during the menstrual cycle and note the woman’s menopausal state as the lower urinary tract has estrogen receptors [22]. Previous continence operations have an important influence on the future success of continence surgery, as the urethral sphincter may be altered by scarring and damage to sphincter innervation by previous vaginal surgery, as well as distortion and narrowing of the bladder neck. Operations on the uterus may interfere with the innervation of the bladder, particularly after radical hysterectomy for carcinoma and radiotherapy.

PAST MEDICAL HISTORY

It is important to record all past major abdominal and pelvic surgery, and urinary complications as a result of the surgery should be noted. The postoperative course can often be revealing, particularly when women have been unable to void spontaneously and required catheterization. This could indicate prolonged overdistension that can lead to voiding difficulties due to detrusor underactivity. Surgery to the spine and any resulting neurological impairment must be recorded. Operations on the large bowel, especially those involving dissection at the side wall of the pelvis, such as abdominoperineal resection of the rectum may result in denervation.

Conditions increasing abdominal pressure, such as chronic cough or constipation, can produce the symptom of stress urinary incontinence and make the problem more severe. Cardiac and renal failure can increase daytime and nighttime voiding frequency through polyuria. Obstructive sleep apnea leads to the release of atrial natriuretic peptide due to cardiac distension caused by the negative pressure environment in the chest. This cardiac hormone increases sodium and water excretion and also inhibits other hormone systems that regulate fluid volume, vasopressin, and the renin–angiotensin–aldosterone complex leading to nocturnal polyuria. Endocrine disorders such as diabetes mellitus or diabetes insipidus may lead to polyuria and polydipsia. Chronic diabetes mellitus can increase frequency as a result of overflow incontinence secondary to a hypotonic detrusor and impaired bladder sensation.

There does appear to be an association between schizophrenia and detrusor overactivity [23]. Additionally, women suffering from dementia may not empty their bladders frequently and may not be aware of the need to void.

The number of proven urinary tract infections during the past 2 years should be recorded. Childhood enuresis after the age of 6 years is particularly important as often these patients have detrusor overactivity.

The obstetric history should include parity, length of labor, mode of delivery, and weight of the largest infant; however, such information may not be useful as the details of labor are not always recalled accurately. Cesarean section or epidural block during labor and the retention of urine postpartum are possible progenitors of voiding difficulties [24,25].

NEUROLOGICAL HISTORY

Many neurological conditions can cause problems for the bladder, bowel, or sexual function. Women should be questioned regarding symptoms of limb weakness or altered sensation. This may be subtle, such as altered sensation during sexual intercourse or an inability to feel their urinary stream during micturition. Women with neurological symptoms may also report the symptom of intermittency. Any history of multiple sclerosis, parkinsonism, spinal cord injury, stroke, or spina bifida should be recorded. Diabetes mellitus and cerebrovascular accidents can also result in symptoms secondary to peripheral neuropathy. Worsening symptoms of back pain with urinary and neurological symptoms warrants a general neurological examination.

DRUG HISTORY

Many drugs affect the lower urinary tract. Diuretics can produce urgency, increased daytime frequency, and urgency urinary incontinence. Benzodiazepines sedate and may cause confusion and secondary incontinence, particularly in elderly patients [27]. Alcohol impairs mobility, produces a diuresis, and can impair the woman’s perception of bladder filling. Drugs that have anticholinergic side effects impair detrusor contractility and may cause urinary retention with secondary overflow incontinence. These include antipsychotic drugs, antidepressants, opiates, antispasmodics, and antiparkinsonian drugs. This could be compounded by other drugs such as beta-3 adrenoceptor agents. Drugs that improve bladder storage are shown in Table 28.7.

Sympathomimetic drugs, often found in cold remedies, can increase the urethral sphincter resistance and produce voiding difficulty. Alpha-adrenergic blockers, such as doxazosin used to treat hypertension, may have cause bladder smooth muscle or urethral relaxation and resultant stress urinary incontinence [26,27]. Cystitis is a common complication of chemotherapy treatment, and hemorrhagic cystitis can result from certain types of antineoplastic treatment. Chemotherapy-induced cystitis can arise from agents directly instilled into the bladder as part of a treatment program for superficial cancer of the bladder or from toxic metabolites of renally excreted antineoplastic agents, which come in contact with the bladder. Drugs that improve bladder emptying are shown in Table 28.8.

Table 28.7 Drugs That Improve Urine Storage

- Anticholinergic drugs
  - Propantheline bromide
  - Emepronium bromide/carrageenate
  - Tolterodine
  - Darifenacin
  - Solifenacin
- Musculotropic drugs
  - Oxybutynin chloride
  - Dicycloverine chloride
  - Flavoxate hydrochloride
- Calcium antagonists
  - Nifedipine
  - Flunarizine
- Tricyclic antidepressants
  - Imipramine
  - Doxepin
- b-adrenoceptor agonists
  - Mirabegron
  - Terbutaline
  - Salbutamol
  - Isoprenaline
- a-adrenoceptor antagonists
  - Phenoxybenzamine
  - Prazosin
- Prostaglandin synthetase inhibitors
  - Flurbiprofen
  - Indomethacin
- Neurotoxins
  - Capsaicin
  - Resiniferatoxin
- Drugs reducing urine production
  - Desmopressin
- Drugs increasing outlet resistance
  - a-adrenergic agonists
    - Phenylpropanolamine hydrochloride
    - Midodrine
  - Serotonin–noradrenaline reuptake inhibitors
    - Duloxetine
  - b-adrenergic antagonist
    - Propranolol
- Estrogens

Table 28.8 Drugs That Improve Bladder Emptying

Increased detrusor contractility
Cholinergic agents
Carbachol
Bethanechol
Anticholinesterase
Distigmine
Prostaglandins
$E2_{\alpha}$
$F2_{\alpha}$
Decreased outlet resistance
a-sympathetic blocking agents
Phenoxybenzamine
Phentolamine
Prazosin
Striated muscle relaxants
Baclofen
Dantrolene
Lisidonal
Diazepam

More recently, questionnaires assessing goals and expectations have been developed and validated in a number of languages. They appear to show some promise in an open-label study of treating patients suffering from overactive bladder [28–30].

EXAMINATION

Before examining the woman, it is important to reassure her about the possibility of urinary leakage and explain that she should not be embarrassed as a result of this. The woman’s mobility and mental state play a role in her ability to react to her incontinence problem and may influence management. A minimental state examination can be performed, as well an assessment of the woman’s motivation and manual dexterity, as these may influence her compliance with possible treatments and follow-up.

Abdominal examination precedes vaginal assessment. Inspection will reveal evidence of previous abdominal surgery, and palpation may demonstrate the presence of a full or distended bladder as well as other abdominal or pelvic masses or elicit pain. It is important to perform a screening neurological examination testing the tone, strength, and movement of the lower limbs. It is particularly useful to test the abduction and spreading of toes as the innervation for the lateral abductors comes from S3. The anal tone should be assessed. In women with neurological disease, the presence of the bulbocavernosus reflex (reflex contraction of the anal sphincter elicited by gentle tapping of the clitoris) indicates that sensory and motor pathways related to the urogenital tract are intact. Additionally, a voluntary cough should cause a reflex contraction of the anal sphincter. An intact sacral reflex can be tested by stroking the skin lateral to the anus, which should elicit a contraction of the external anal sphincter.

GYNECOLOGICAL EXAMINATION

The condition of the vulval skin is important as there may be signs of excoriation, edema, or erythema due to exposure of the skin to urine on the vulva for prolonged periods of time and concomitant candidiasis. Vaginal atrophy, particularly in women more than 10 years after the menopause, may be seen. The skin has deep rugae where the skin is rubbing on underwear secondary to vaginal prolapse.

Genital prolapse can now be assessed using the methods produced by the ICS and IUGA’s most recent report on the standardization of terminology [1]. It suggests that women should be assessed with an empty bladder and ideally an empty rectum because an increased bladder volume can restrict the degree of descent of the vaginal prolapse. Any cystocele, rectocele, uterine, or vault descent can be best assessed in the Sims’ (left lateral) position on coughing and straining using a Sims’ speculum. Alternatively, examination may also be made in lithotomy using the lower blade of a Graves’ speculum to assist in assessing the opposite vaginal wall [31]. Women may also be examined standing and this may be the only way for a vaginal prolapse to be demonstrated successfully [32]. The best position is one which the woman feels best reproduces her prolapse. After the examination for pelvic organ prolapse, the clinician should report the degree of prolapse in terms of the descent of the anterior and posterior vaginal walls, as well as the cervix, or in the case of a woman who has had a hysterectomy, the vaginal vault. Various staging or grading methods have been described and the level of the hymen is usually used. The pelvic organ prolapse quantification system is a validated method that involves using a measuring device marked in centimeters to measure specific points on the anterior and posterior vaginal wall as well as the descent of the cervix or vaginal cuff allowing quantification of the degree of vaginal prolapse [33]. This method allows prolapse staging from 0 to IV where 0 is no prolapse, stages I to III are increased descent of the prolapse through the vagina, and stage IV is complete eversion of the total length of the genital tract. Women can be reproducibly examined in the left lateral and standing positions [32]. The vagina should also be examined for evidence of atrophy, inflammation, pain, or scarring from previous surgical procedures. Other aspects of pelvic examination include examination of the urethra where urethral mucosal prolapse or a caruncle may be seen. A urethral diverticulum may present with a midline anterior vaginal wall swelling or with tenderness over the length of the urethra as well as postmicturition leakage. Vaginal cysts such as Gartner's duct cyst may present with similar findings. If a woman is complaining of a discharge or has had a recent onset of symptoms of urgency and frequency, it may be useful to obtain swabs to culture for *Chlamydia*, atypical organisms, or gonococcus. A bimanual examination should be performed to exclude abnormal pelvic organs, masses, or uterine impaction and can exclude a large postmicturition urinary residual. Pelvic masses such as ovarian cysts and uterine enlargement greater than 12 weeks size can cause pressure symptoms on the bladder and rectum resulting in urinary frequency or retention; often, the symptoms resolve once the mass has been removed.

Table 28.9 Modified Oxford Scale

Grade 0: No discernable PFM contraction
Grade 1: A flicker or pulsing under the examining finger—a very weak contraction
Grade 2: A weak contraction—an increase in tension in the muscle without any discernable lift or squeeze
Grade 3: A moderate contraction—characterized by a degree of lifting of the posterior vaginal wall and squeezing on the base of the finger with indrawing of the perineum
Grade 4: A good PFM contraction producing elevation of the posterior vaginal wall against resistance and indrawing of the perineum
Grade 5: A strong contraction of the PFM

Pelvic floor muscle (PFM) examination may be appropriate that assesses tone at rest and strength with voluntary and reflex contraction. This may be assessed with digital palpation circumferentially. The ICS has produced a standardized document that details PFM assessment [34], and the Oxford classification has been used as a simple clinical assessment [35] (Table 28.9). If pelvic pain is a problem, it is important that a digital examination is performed to assess where the pain originates and in particular to determine trigger points in the levator ani and also tenderness upon palpation of the pelvic organs adjacent to the vagina. The PFM hyperalgesia scoring system has been proposed as a validated method of pelvic floor assessment in women with chronic pelvic pain [36]. Finally, rectal examination is particularly important in the elderly to exclude fecal impaction, which can aggravate urinary incontinence.

CONCLUSION

History and examination alone cannot diagnose female urinary disorders but are used to guide future investigation and management. The method in which symptoms are ascertained may alter the results and self-completed questionnaires seem to be the best. It is important to use reproducible and validated questionnaires as symptoms alone have become the basis of conservative management and have been suggested as indicators for the surgical treatment of pure stress incontinence. In some cases, an obvious cause can be found and treated, thus potentially avoiding the need for further investigations.

29 Bladder Diary and Symptom Scores

Alan Uren and Nikki Cotterill

INTRODUCTION

Patients that present with lower urinary tract dysfunction can complain of a variety of symptoms. However, lower urinary tract and voiding disorder symptoms are notoriously unreliable for an accurate diagnosis [1–3]. There are a number of approaches that a clinician may employ in order to lend some objectivity to the formulation of clinical hypotheses, of which patient-reported outcome (PRO) measures are gaining increasing importance. Symptom scores calculated through the completion of PRO questionnaires are also important for initial diagnostic and outcome assessment. Follow-up questionnaires also allow the monitoring of any improvement, placing the patient's lived experience at the center of ongoing evaluation.

URINARY DIARY

One of the most commonly used methods of investigating a patient's symptoms is by the completion of a urinary diary (UD). It is typically completed by the patient over a number of days prior to the visit to the doctor and records information such as the times of micturition, voided volumes, and fluid intake. The use of such tools is stipulated in the guideline algorithms in the assessment of lower urinary tract symptoms (LUTS) and incontinence. The UK National Institute for Health and Care Excellence (NICE) currently recommends their use for the initial assessment of women presenting with urinary incontinence or overactive bladder [4]. However, despite the value of bladder diaries for clinical diagnosis and patient management, an audit by the Royal College of Physicians [5] concluded that bladder diaries are often underused in primary and acute care.

Although the UD in various formats has been used extensively as a clinical tool for many years [6], until recently there has been very little attempt at formal diary development and validation [7]. The format and content of a UD is often left to the discretion of the clinician so as a result, many different diaries are currently in use [8]. The International Continence Society (ICS) recognizes three types of UDs in terms of the parameters that are recorded [9]:

1. Micturition chart records the times of micturition, day and night, for a period of at least 24 hours.
2. Frequency–volume chart (FVC) records the voided volumes as well as the times of micturition, day and night, for at least 24 hours.
3. Bladder diary records the voided volumes and times of micturition as well as other information, day and night, for at least 24 hours.

A large number of additional parameters have been suggested for inclusion in a bladder diary (e.g., pad use or fluid intake). However, there is a balance between collecting enough useful clinical information and minimizing any burden placed on the patient during completion [2]. Bright et al. [8] collated patient and clinician opinions in order to identify the content thought essential. Over 30 different parameters were considered, but time of void, volume of void, fluid intake, time and amount of incontinence were deemed to be the most important parameters for the utility of a generic bladder diary. Pad use and bladder sensation are also considered important information, as these can have a significant effect on the quality of life of the patient.

DURATION

Studies that investigate optimal diary duration have shown that a UD that is too short may not capture the desired information, whereas one that is too long may reduce patient compliance, resulting in poor completion rates [2,10,11]. Several studies explore optimum diary duration [2,10–12] and vary from 24 hours to 7 days in length [7].

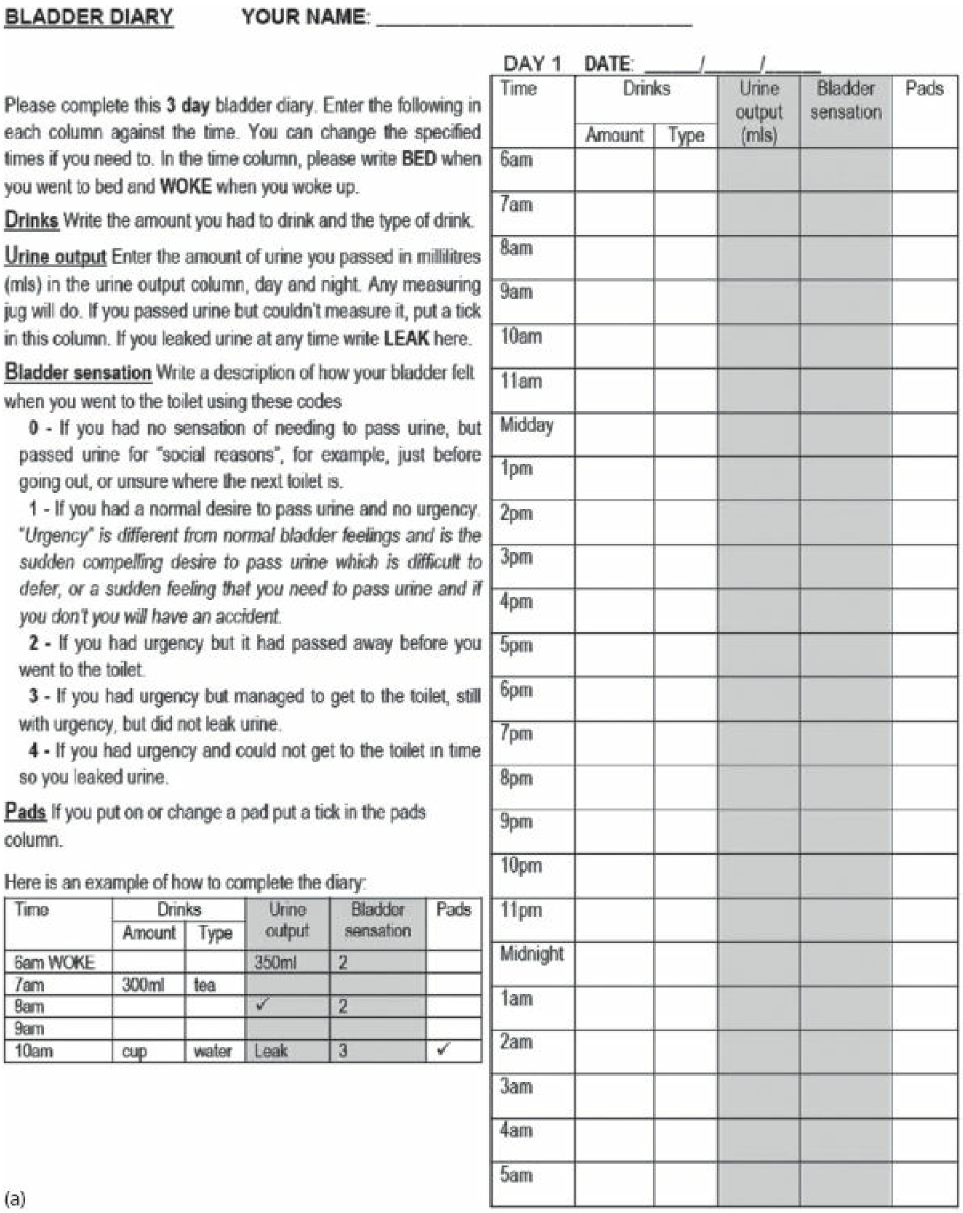
There are no clear guidelines for the optimal duration of record keeping. However, a 3-day or 4-day FVC or diary for day-to-day use in clinical practice is suitable for the assessment of LUTS [8]. It is also recognized that a 1-day FVC can sometimes be sufficient to gain insight into daily voiding habits, but a 7-day diary may be required for "atypical clinical patterns or research." The current NICE guidelines recommend the diary should be of at least 3 days duration and cover both work and leisure days to represent variations in their usual activities [4].

ICIQ BLADDER DIARY

A comprehensive validation process for a standardized patient reported measure is required when introducing new assessment tools for their acceptance in the guidelines and regulatory context. Validation should include the "assessment of content, construct and criterion validity, and analysis of reliability and responsiveness" [7]. Until recently, no fully validated diaries existed. However, following a review of the existing literature [7], a 3-day diary has been developed and subjected to the full psychometric validation protocol used to develop the International Consultation on Incontinence Questionnaire (ICIQ) modules [13]. It is accepted as the "ICIQ bladder diary [14] (Figure 29.1)." The final UD records urinary frequency, voided volume, and fluid intake (including type, time, and amount). The time of each event is recorded next to the time covering the full 24 hours for each of the 3 days. In addition to this, there is a column in which to record the bladder sensation score, included within the diary, which allows the patient to describe their sensation of urgency for each micturition. The versatility of the diary is also improved by the inclusion of a further column to record pad use. Although it is recognized that no diary is likely to be "one size fits all," following the rigorous validation process, the ICIQ bladder diary is accepted as being a good generic diary to assess patients with LUTS for day-to-day clinical practice.

ELECTRONIC DIARIES

The development of an electronic diary is particularly relevant when considering the rapid increase of electronic technology both in clinical practice and within our society. There are several potential advantages for the use of an electronic bladder diary. Primarily, it facilitates data entry and allows automatic calculation, allowing the immediate review of the essential parameters by the clinician. This has the potential to reduce the workload in busy clinics, reduce calculation errors, and ultimately improve clinical outcomes. A recent pilot study using a sample of 22 patients tested the clinical utility of a handheld electronic diary [15]. The accuracy of the report was 58% when calculated manually from the paper version, compared with 100% accuracy when electronically calculated. In addition, the handheld electronic diary was preferred by 81% of patients over the paper diary with reasons given such as "saves time" and "easier to complete." This preference by some patients for an electronic diary is supported by previous studies [16,17]. However, it is recognized that a definitive study in order to test this electronic diary equivalence is required, particularly noting that younger people are more likely to adopt such approaches more readily than the elderly. An electronically based adaptation of a paper-based diary must be shown to produce data that are of at least equivalent or higher reliability. This may be shown through full psychometric testing [18].



BLADDER DIARY **YOUR NAME:** ______________________________

Please complete this **3 day** bladder diary. Enter the following in each column against the time. You can change the specified times if you need to. In the time column, please write **BED** when you went to bed and **WOKE** when you woke up.

Drinks Write the amount you had to drink and the type of drink.

Urine output Enter the amount of urine you passed in millilitres (mls) in the urine output column, day and night. Any measuring jug will do. If you passed urine but couldn't measure it, put a tick in this column. If you leaked urine at any time write **LEAK** here.

Bladder sensation Write a description of how your bladder felt when you went to the toilet using these codes

0 - If you had no sensation of needing to pass urine, but passed urine for "social reasons", for example, just before going out, or unsure where the next toilet is.

1 - If you had a normal desire to pass urine and no urgency. *"Urgency" is different from normal bladder feelings and is the sudden compelling desire to pass urine which is difficult to defer, or a sudden feeling that you need to pass urine and if you don't you will have an accident.*

2 - If you had urgency but it had passed away before you went to the toilet.

3 - If you had urgency but managed to get to the toilet, still with urgency, but did not leak urine.

4 - If you had urgency and could not get to the toilet in time so you leaked urine.

Pads If you put on or change a pad put a tick in the pads column.

Here is an example of how to complete the diary:

Time	Drinks		Urine output	Bladder sensation	Pads
	Amount	Type			
6am WOKE			350ml	2	
7am	300ml	tea			
8am			✓	2	
9am					
10am	cup	water	Leak	3	✓

Figure 29.1 International Consultation on Incontinence Questionnaire bladder diary developed by Bright et al. [14].

NORMATIVE VALUES

A number of studies have attempted to provide a reference range for the parameters calculated from voiding diary data [19–24]. However, all parameters are extremely variable so actually defining what is considered "normal" presents challenges [23–25]. There is also considerable overlap in the range of what may be considered "normal limits" between asymptomatic patients and symptomatic patients [24,26,27]. Table 29.1 represents the values obtained from populations of asymptomatic volunteers as reported in the published literature.

Further to this variability, independent studies by Amundsen et al. [24] and van Haarst et al. [23] show that in asymptomatic females, as the age of the patient increases, the volume/void decreases and the frequency increases. For example, an older woman of 70 years old is likely to have a higher frequency and smaller volume/void than a 20-year-old woman. In addition to this, independent of age, there is a positive relationship between maximum volume voided during the day (functional bladder capacity) and the total 24 hour volume. Here, a woman who voids a large amount over 24 hours is likely to have a higher frequency and larger volume per void than a woman of similar age who only voids a smaller amount over 24 hours. One hypothesis is that this may be an adaptation to keep the voiding frequency relatively constant by adjusting the bladder capacity to compensate for changes in fluid intake. Nevertheless, these relationships have implications for the clinical interpretation of bladder diaries.

Table 29.1 "Normal Limit" Range Obtained from Populations of Asymptomatic Patients as Reported in Published Literature

	Pauwels et al.	De Wacter and Wyndaele	Kassis and Schick	Pfisterer et al.	Amundsen et al.	Range considered normal[c]
No. of women volunteers	22	15	33	24	161	
Mean age (years)	49	21	40	50.2	48	
Daytime frequency	6.49	7.24 ± 2.27	5.63 ± 1.26	5.7(4.3–8)	7.1 ± 1.9[a]	4–8
No. of nocturia episodes	0.07	0.07	0.08 ± 0.16	0.2(0–1)		0–1
Mean vol/void during day (mL)	289 ± 178	231 ± 128	237 ± 67	267(212–297)	245 ± 91[b]	150–350
Mean vol/void during night (mL)	450 ± 189	300 ± 50	379 ± 132	325(219–404)		220–550
Mean VV in 24 hours (mL) ± SD	1961			1442(1288–2239)	1730 ± 721	1000–2400

Source: Adapted from Al Afraa T et al., *Int Urogynecol J*, 23, 681, 2012.

Note: Values are presented as mean ± standard deviation and for Pfisterer et al., the median and interquartile range.

[a] Value represents frequency over 24 hours.

[b] Value represents average voided volume over 24 hours.

[c] Approximate range taken from values obtained from the literature shown.

Amundsen et al. argue that as age and the total 24 hour voided volume influence the functional bladder capacity, it is necessary to adjust for these parameters. Table 29.2 shows the voiding frequency, mean 24 hour voided volume, and maximum 24 hour voided volume after adjusting for age and 24 hour volume by subjecting the data to multiple regression analysis. As might be expected, even after adjustment, the voiding frequency still increases with both age and voided volume over 24 hours. However, it is reported to reduce the variability of the frequency and functional bladder capacity by about 25% and 50%, respectively. Here, correcting for age and fluid intake increases the sensitivity of the diary to detect increased frequency and reduced FBC.

SYMPTOM SCORES

Further information about symptoms may be collected by the completion of a PRO questionnaire [28]. This usually includes some assessment of the impact on the quality of life, as well as the perceived severity of symptoms as reported by the patient. A scoring scheme for each question provides some quantification of the severity of symptoms and may also be used to evaluate the effectiveness of any management strategy at a later stage [14,29]. Information gathered from symptom scores combined with the UD forms the basis for the consultation by which the clinician attempts to reach a provisional diagnosis before proceeding with any necessary further diagnostic testing. Despite this, an audit by the Royal College of Physicians [5] found that over a quarter of acute care patients did not have their urinary symptoms recorded. An assessment of the impact of incontinence on the quality of life was recorded in only 69% of primary care and 25% of acute care patients.

Although PRO measures are widely used in order to assess patient perspectives [30], several clinician-completed scores are also available [31,32]. However, it is acknowledged that there is likely to be the potential for bias introduced by the interviewer [33] and the agreement between patients and clinicians regarding satisfaction with treatment outcomes is known to be poor [34]. There is also a direct relationship between patient satisfaction and the fulfillment of treatment expectations [35]. For this reason, the emphasis in current clinical practice is capturing the patients' lived experience rather than from the clinicians' perspective.

VALIDITY AND RELIABILITY

Consideration of the development and validation studies employed to develop symptom scores is essential given their importance for clinical assessment [36–38]. Section 2 provides a detailed discussion of how PRO questionnaires are developed, but it is important to ensure that clinical symptom scores have published evidence of their

- Validity (appropriateness and acceptability to the population of interest)
- Reliability (homogeneity and stability over time)
- Responsiveness (ability to detect change) where outcome following intervention is to be evaluated

Individual symptom score selection will depend on a number of factors including the intended population and symptoms to be evaluated. It is important that the choice of questionnaire is appropriate to the intended use. Section 2 covers the variety of questionnaires that are available and provides some guidance as to the content covered by the available questionnaires in clinical use.

Table 29.2 “Normal” Values for 24 Hour Frequency, Mean Voided Volume and Maximum Voided Volume in Asymptomatic Women as Published in Amundsen et al. [24], When Adjusted for Age and 24 Hours Volume by Subjecting the Data to Multiple Regression Analysis

	24 hour volume (mL)					
Age	1000	1500	2000	2500	3000	3500
24 hour frequency						
20	8.7	9.3	9.9	10.5	11.2	11.8
30	8.8	9.4	10.1	10.7	11.3	11.9
40	9.0	9.6	10.2	10.8	11.5	12.1

70	188	268	358	447	537	626
80	179	260	349	439	528	618

CONCLUSION

The UD, or more specifically the bladder diary, is accepted as being an integral tool in the initial assessment of women with LUTS. A number of diaries are available for clinical use but the ICIQ bladder diary is currently the only fully validated UD. The most recent research suggests optimum diary duration of 3 or 4 days in order to strike balance between capturing the necessary information and not placing any unnecessary burden upon the patient. Electronic diaries are showing promise but still require full psychometric evaluation. Normative values calculated from bladder diaries are extremely variable, but recent research has reduced this uncertainty by providing parameter-adjusted reference tables.

Symptom scores from validated PRO questionnaires are now widely used in preference to clinician-completed scores in order to capture the patients' lived experience. When used in combination with information from a bladder diary, these are essential tools for initial investigation of LUTS.

Pad Tests

Marie-Andrée Harvey

HISTORICAL ASPECTS

James et al. first described in 1971 the quantification of urine loss to determine response before and after treatment [1]. This was achieved using a pair of elongated electrodes embedded within the absorbent layer of a diaper, which contained dry electrolytes. Following urine loss, the moisture between electrodes resulted in a change in electrical conductivity that could be detected and recorded. It was marketed under the name of Urilos (N. H. Eastwood & Son, Ltd, London, England) [2]. However, the equipment was rather cumbersome and never caught on.

The pad test as we know it today was originally simultaneously described by Sutherst et al. and by Walsh and Mills [3,4]. It consists of the use of a perineal pad to document urinary incontinence and quantify its severity quantitatively, under natural conditions. The amount of loss is calculated by subtracting the weight of the pad before the test from its weight after the end of the test. A standardized 1-hour pad test (see Table 30.1) was then proposed in 1983 [5] and endorsed by the International Continence Society (ICS) in 1988 [6].

Other innovative methods were developed, going from the distal urethral electrical conductance test (DUEC) [7,8] to temperature-sensitive device [9]. The DUEC involves a 7 Fr catheter placed in the distal urethra, on which two rings, mounted 1 mm apart, register the electric potential change occurring when fluid gets into contact with the electrodes. The temperature-sensitive device uses a diode temperature sensor imbedded in the outermost layer of a pad, which records a change in voltage across the diode when urine (warmer than the perineum) is lost. These two methods are devised to detect urine leakage during ambulatory urodynamic studies without the bulk of the Urilos but are unable to quantify loss.

The clinical use of these devices has never been evaluated and their accuracy was disputed. The Urilos was said to be able to detect volumes from less than 1 mL to approximately 100 mL, with a variation of up to 20% when repeated. In subsequent reliability studies, the difference in volume recorded between different nappies varied between 13% [2] and 25% [10]. When comparing nappies from different boxes, the variation between them was as much as 68% [10]. Furthermore, the Urilos was noted to be more uncomfortable and not to absorb large volumes of fluid [11]. Consequently, the Urilos nappy never gained widespread popularity. The DUEC test has experienced a similar fate. In a small study comparing the ICS pad test to the DUEC, the DUEC showed no benefit over the 1-hour ICS pad test, with a greater complexity involved [12]. A recent study [13] evaluated its role in the diagnosis of women with symptoms of stress urinary incontinence (SUI) but without demonstrable leak on urodynamic or cough stress test (in which a leak is observed when coughing with a comfortably full bladder). While it detected SUI in 28% of symptomatic women with negative urodynamic studies, the DUEC test failed to detect stress incontinence in 33% of symptomatic women with demonstrable stress incontinence during standard urodynamic study.

INDICATIONS

A pad test can be used in two manners: as an objective means of detection of urine leakage when clinical testing is otherwise negative or to quantify urine loss prospectively in the clinical or investigational settings. It will not, however, diagnose the type of urinary incontinence [14,15]. The objective demonstration of urinary incontinence is of importance in its diagnosis and should be part of the clinical assessment of all patients with incontinence [16], and adding a pad test likely improves the identification of a woman with SUI [17]. It may be of particular value during research studies for the objective evaluation of treatment response [18]. Neither the patient’s perception of incontinence [2] nor her perception of its severity [19] is well correlated with urodynamic measures.

Pad tests are generally divided into short (<1, 1, 2 hours) or long (24, 48 hours). Standardization only exists for the ICS 1-hour pad test [6]. Short pad tests are easily performed in an outpatient clinical setting [20]. Long pad test protocols have, as yet, not been subject to standardization. A pad test should not be done during menstruation.

RELIABILITY AND VALIDITY

> Before one can obtain evidence that an instrument is measuring what is it intended, it is first necessary to gather evidence that [it] is measuring something in reproducible fashion; it says nothing about what is being measured. To determine that the test is measuring what was intended requires some evidence of "validity" [21].

> Validity expresses the relation between observed measurements and the true state of the entity being studied [22].

Reliability can be defined broadly by two characteristics: internal consistency and stability [21]. As internal consistency represents the average of the correlations (e.g., Cronbach's alpha) among all items in the instrument (e.g., questionnaire with multiple questions), this would not apply to assess reliability for the pad test. In this case, reliability is best demonstrated through its stability, i.e., the degree of agreement between different observers (interobserver reliability), between observations made by the same observer on two different occasions (intraobserver reliability), or between observations on the same patient on two distinct occasions, separated by a time interval (test–retest reliability).

Table 30.1 Standardized 1-Hour Pad Test

0 minute
- Apply preweighed pad
- Drink 500 cc sodium-free liquid
- Sit and rest

30 minutes
- Walk and stairs climbing

45 minutes
- Activities: Sit/stand × 10
- Cough × 10
- Run in place × 1 minute
- Pick up objects from floor
- Wash hands under running water × 1 minute

60 minutes
- Collect and weigh pad
- Patient voids, volume measured

The second dimension that is important in an instrument is its validity. Validity seeks to determine that the tool is measuring what it is intended to measure (urine loss) and does so by comparing the performance of a new tool against that of a known tool, a "gold standard." When such standard is nonexistent, validity can be obtained by comparison with other tools or "constructed." In the former situation, the current tool is compared to other tools testing the same or similar condition. This is usually referred to as *criterion, convergent*, or *concurrent validity* and, in the case of pad test, can be achieved by comparing pad tests to symptom questionnaires, urodynamic studies, or other validated pad tests. *Construct validity* is achieved by studying two or more different (e.g., continent versus incontinent) or similar populations in which it is expected to find a difference or similarity, respectively, between test results. Validity of the pad test can further be reflected by the accuracy of the measured volume lost and its sensitivity in detecting such a loss. If the sensitivity is poor, the test will at times not detect the true state of the entity, namely the presence of incontinence. However, as there is currently no means of detecting the true amount of urine leak with each incontinence episode, the validity of the pad test will be reflected in its ability to demonstrate incontinence in a patient who complains of urinary incontinence and a lack of urine loss in patients who report continence.

SHORT PAD TESTS

This category includes the following tests: standardized ICS 1-hour pad test; modified version of the ICS 1-hour test, usually incorporating different exercise intensity; or pad tests <1 hour, using a fixed bladder volume, with retrograde filling (through a temporary urethral catheter).

The type of activity leading to urine loss and the impact of voiding during the test period have been evaluated [23a]. Irrespective of urodynamic diagnosis, activities leading to leakage in all women included (in increasing order of urine loss) walking around/bed-making (3–4 g); climbing stairs up and down, with or without heavy pack (5–6 g); picking objects on the floor (6 g); and spending several minutes hand washing (10 g). Voiding (with the pad removed for the voiding) during the test had no effect on the result, with a similar proportion being dry on the pad test whether they voided or not.

The validity of the pad test in women with postmicturition dribble is unknown as no studies have evaluated the pad test results in affected women, This potentially relevant condition is present between 3.1% [23b] and 4.6% [23c] of women, mostly if they have other LUTS (more often with symptoms compatible with overactive bladder): only 1.5% of women without other LUTS had isolated post micturition dribble [23c]. Perhaps, one should screen for the presence of postmicturition dribble and, if present, recommend a pelvic floor contraction before drying the vulva, as an equivalent to manual urethral compression (“milking”) shown to help men [26d].

Some studies have evaluated the feasibility of a short pad test undertaken at home, where a subject would be given preweighted pads and return the pads in a watertight sealed plastic envelope [24,25]. Mailing delays were not shown to significantly alter the measurement of pad weight.

Detection Limit

Increased weight of the pad test may be due to urine but also to vaginal discharge, sweating, or menstruation. Comparing 50 continent women to 100 incontinent women, a maximum pad weight gain of 1 g was measured in all continent patients versus a mean of 12.2 g in incontinent women [3]. Walsh [4] tested six healthy continent volunteers for three consecutive days from 9 a.m. to 9 p.m., during which pads were changed every 2 hours and reported a 1.2 g/2 hours weight gain due to perspiration. Versi and Cardozo [26] compared the 1-hour pad test to video-urodynamic studies (v-UDS) in 90 continent and 99 UDS-confirmed stress incontinent women. In continent women with normal v-UDS, the mean pad weight gain was 0.4 g, with a 99% upper confidence limit of 1.4 g. These results confirm the validity of the short pad test in its ability to detect incontinence between self-proclaimed continent and incontinent populations.

ICS 1-Hour Pad Test

The ICS 1-hour pad test was set out to define a standardized objective measure, which would facilitate comparison between studies. The ICS fixed the threshold for a negative pad test at <2 g. However, despite earlier favorable reports, the ICS 1-hour test has been subsequently shown to have insufficient reliability [27–29], except in one study [30]. However, a better reproducibility was noted [27] when bladder volume at the start of the test was taken into account. Interobserver [31] and test–retest [29] reliability studies were found to be poor, as shown by wide limits of agreement.

It is important to note that a correlation coefficient merely quantifies *association* between two test results. If the two tests compared measure the same variable, evidently they will be associated, but high association does not necessarily translate to high agreement. The limit of agreement using the Bland and Altman method [32] is a better statistical analysis in describing *agreement* between two tests measuring the same outcome.

Convergent validity of the ICS 1-hour pad test compared to symptoms and quality of life questionnaire has been tested and was generally found to be poor: the International Consultation on Incontinence Short Form Questionnaire (ICIQ-SF) [33,34], Urogenital Distress Inventory (UDI-6) [33], Incontinence Impact Questionnaire (IIQ-6) [33], the Stamey grading scale [33], the King’s Health Questionnaire [35], the Symptom Impact Index and Symptom Severity Index [36], the Urogenital Distress Inventory and the Incontinence Impact Questionnaire [37,38], I-QOL [39], the “patient’s perception of incontinence severity” [35,40], and the frequency of incontinence episodes on diary [15] with at times significant but mostly weak correlations.

Similarly, construct validity testing of the ICS 1-hour pad test when compared to UDS [26,28,37] correctly identifies continent subjects but has a substantial false-negative rate in incontinent women (6%–32%), except in one study [41], where all 42 women were correctly identified. Versi et al. studied a further 311 additional women presenting with urinary complaints and failed to show that the test could screen for the pathology found on v-UDS, as the sensitivity was poor (68%) [42]. The measure of agreement (kappa's coefficient) between the pad test and the presence of pathology on UDS denoted a moderate agreement [43]. Studies evaluating the relationship between the ICS 1-hour pad test and specific urodynamic measures of urethral integrity reported a weak but significant negative correlation between the urine loss on pad test and the Valsalva leak point pressure (VLPP) in some studies [44,45] but not in others [46] and a correlation with maximal urethral closure pressure (MUCP) [37]. That is, with increasing urine loss on pad testing, the VLPP decreased and MUCP decreased. The correlation with MUCP was weak and not found in other studies. The urodynamic diagnosis has a variable effect on pad weight. In one study, women with urodynamic stress incontinence have greater leakage on 1-hour pad testing than those with detrusor overactivity; however, the amount of loss was not discriminatory of urodynamic diagnosis [15]. The opposite was noted elsewhere [14].

Assuming that UDS would represent the gold standard, the pad test seems to be able to most of the time discriminate between continent and incontinent women (construct validity); a positive test correctly identifies an incontinent patient, but a negative test may be found in women demonstrated to be incontinent on UDS. It is unable to discriminate among the different incontinence pathologies found on UDS or to consistently determine incontinence severity when compared to v-UDS studies [26,42]. However, a strong correlation was noted between the Stamey incontinence grading and the 1-hour pad test in a study including 320 women with stress or mixed urinary incontinence symptoms [47]. The pad test was slightly modified, whereby serial ultrasound was obtained to confirm a minimal bladder volume of 300 mL, at which time the prescribed exercises were completed within a 10 minutes window. Accuracy of the 1-hour pad test was measured using an ROC curve. The threshold between mild and moderate was found to be 3.4 g (sensitivity 79.7%, specificity 91.6%) and between moderate to severe, 10.2 g (sensitivity 82.7%, specificity 89.6%), with excellent area under the curve (0.908 and 0.900, respectively) (0.5 represents a worthless test and 0.9–1, an excellent one). The authors concluded that based on the 1-hour pad test, women with less than 3 g were considered to have mild incontinence, 3–10 g moderate, and >10 g severe incontinence.

Pad tests may also help predict surgical outcome: women with more severe SUI as judged by weight gain on 1-hour pad test were shown to respond more poorly to surgical repair (87.1 g ± 8.2 vs. 29.8 g ± 2.8, $p < 0.05$) [45,48]. This may be more significant for women with pure stress incontinence, compared to those with mixed symptomatology [45,49].

The 1-hour pad test that is sensitive to change was used as an outcome measure in therapeutic trials [50,51].

The importance of a negative pad test as an outcome measure following therapy varies considerably between patients, nurses, and physicians. Patients scored the importance of an objective success (as determined by a dry pad test) as 67 on a visual 100 mm analogue scale, whereas physicians rated the importance of a dry pad test 53 on the VAS and nurses were the least convinced that a dry pad test was important (score of 28 on 100 mm VAS) [52]. The role of pad testing in outcome research remains to be determined [53].

In light of its limited reliability, it may not come as a surprise that, although endorsed by the ICS, the ICS 1-hour pad test is only rarely (33%) used in outcome research [54]. Surprisingly, despite reports of its poor reproducibility, high urine loss detected on the pad test nevertheless influences clinicians in selecting a surgical treatment option rather than a conservative management [55]. Furthermore, when used in the research setting, women tend to be less compliant with the study protocol when follow-up involves a pad test and a diary [56].

Modified 1-Hour Pad Tests

Consequently, some have sought to improve the reliability of 1-hour pad test, through increasing exercise intensity or controlling the bladder volume.

Validity studies on modified 1-hour pad tests are limited. A study of short-duration pad testing with standard volume reported only a weak correlation with symptoms (recall of number of clothing changes) [57].

There is insufficient data to stipulate that an aggressive protocol adds any reliability or sensitivity to the current 1-hour test. Subjects were asked to drink 1 L of water in 15 minutes. One hour after starting drinking, they were asked to drink an additional 500 mL [58]. Pad testing was started as soon as the subject felt they had a full bladder. A total of 14 different vigorous exercises were performed. At the end of the test, voided volume was measured. Exercises included, but were not limited to, star jumps, sprinting, vacuuming, lifting, carrying and putting down a 10 kg box, and pulling on an elastic band, in addition to standard exercises as included in the ICS 1-hour pad test. None of the 18 controls reported or demonstrated any leakage. Among the 25 women with symptoms of urinary incontinence tested, eight (32%) still had a negative test. Test–retest was obtained in 16 of the 25 women, with a correlation of 0.73.

Reproducibility studies have demonstrated an improved correlation when fixed bladder volume was used. Subjects have significantly more urine loss with increased bladder volume [27,59]. Using a fixed 250 cc bladder volume, a 20 minute pad test is more sensitive than the ICS 1-hour pad test [60]. Performing the pad test once a strong desire (mean 292 mL) is reached further improves sensitivity of the short pad test [61]. At 200 cc, a modified 1-hour pad test did not correlate with leak point pressure [38].

Test–retest reliability of a fixed-bladder volume short pad test shows a substantial difference in the test and retest pad weight, limiting reliability. Although correlations between tests were generally good [14], such measure of agreement is generally a poor choice when the two tests compared are the same (see earlier discussion). When looking at the limit of agreement [32] a considerable variability (± 24–30 g) was noted, with authors admitting that sensitivity was "hardly much better" than the ICS 1-hour [62]. The difference in mean pad weight was significantly different between the test and the retest (9 g), thus limiting the test reliability. A similar result was reported when the bladder is filled at 75% capacity [63], at 50% capacity [62,64], and at 300 cc [65].

Impact of Pelvic Organ Prolapse on the Short Pad Test

Thus far, most studies evaluating the value of the 1-hour pad test have excluded women with pelvic organ prolapse. In a recent pilot study, Chang et al. [66] studied 27 women with stage II or more anterior wall prolapse who had a negative 20 minutes pad test when unreduced and inserted a 10 cm rolled vaginal gauze (20 × 40 cm) before repeating the pad test. Those with a pad test ≥8 g were deemed eligible for a midurethral sling. The number of women who had no evidence of occult incontinence (i.e., incontinence only discerned when any prolapse is reduced) and did not receive a midurethral sling is 23, except for 2, who did at the surgeon's discretion. Only one requested a sling after prolapse surgery. Four women had occult incontinence and received a sling; of those, none required a second sling. Unfortunately, the continence status of the 27 women after their prolapse surgery was not reported. Additionally, the pad test result appears to be affected by the presence of advanced prolapse [37]. Costantini et al. found that women with voiding difficulties were more likely to have a negative pad test compared to those without these difficulties. Furthermore, the majority of women with voiding difficulties had an anterior wall prolapse grade 3 or greater, which contrasted with women without voiding difficulties whose majority had no such advanced prolapse. They postulated that women with advanced anterior wall prolapse seemed to experience a "physical obstacle against urine leakage."

The committee on Imaging and Other Investigations from the fifth International Consultation on Incontinence [67] concluded that the 1-hour pad test was not very accurate, unless done at fixed bladder volume and with set exercises. Consequently, it was deemed an optional investigational tool in the routine evaluation of incontinence, while being considered useful in outcome research. Standards suggested included a 20–60 minutes, fixed volume bladder pad test, with a positive test being a pad weight gain ≥1 g.

Pyridium Test

Phenazopyridine hydrochloride (Pyridium^{TM}, Parke–Davis) ingestion results in renal excretion of the dye with orange coloring of the urine. It has been used by clinicians to detect incontinence using the compound's property of coloring urine orange. Wall et al. [41] reported the sensitivity and specificity of Pyridium as a qualitative test in incontinent patients. While very sensitive, the addition of pyridium was not specific. The poor specificity was due to a high false-positive rate in asymptomatic patients. This may be explained by staining of the perineum at the time of a prior void, resulting in tinting of a subsequent pad on vulvar contact, or by a minimal, nonclinically significant, loss of urine in normal women. These results were subsequently confirmed in a study testing continent (self-reported) women, during exercise [68], in which Pyridium staining was noted in nearly 100% of subjects after physical activity was conducted, with a mean pad weight of 4.59 ± 3.55 g (outdoor exercise) or 1.33 ± 0.97 g (indoor exercise). Pyridium staining was minimal, with a mean stained area of 2.66 mm (range 0–11 mm). No cutoff limit in the pad weight has been previously established to define a normal pad test during exercise, given that there would be a greater weight gain due to perspiration alone.

In the light of these reports, the use of pyridium in detecting transurethral incontinence can be perceived as unreliable and nonspecific.

LONG-DURATION PAD TESTS

The 1-hour pad test has been criticized because of its artificial setting and short duration. A longer pad test was first described by Sutherst's group, in an abstract form [69]. However, the aim of the study then was to determine if the 1-hour pad test was representative of urine loss experienced during regular activity, not to assess if it was better in detecting and quantifying incontinence than its shorter counterpart. It was suggested by Lose et al. that performing a test during regular daily activities would be more sensitive than during a single 1-hour test [70]. However, the pad test result is influenced by the intensity of the activity, even between "minimal" (5.2 g) and "normal" (9.9 g) activities [71].

Generally, a long-duration pad test is performed at home, during a typical day's activities. The subject is given a number of preweighted pads, placed in individually sealed envelopes. She is instructed to wear pads consecutively for a given period (12, 24, 48 or 72 hours) and to return the pads in their sealed envelope for weighing. The use of sealed plastic bags for storage of used pads did not alter significantly the results [72,73]. The 24-hour pad test showed only limited diagnostic value for self-reporting of incontinence in pregnancy or postpartum [74].

Detection Limit

Lose et al. first established a detection limit by studying 23 asymptomatic female subjects [70]. They noted that the median weight obtained for the 24-hour pad test was 4.0 g, with a 99% upper limit of 8 g for the 24-hour period. Ryhammer et al. [75] studied 78 self-reported continent women. Their mean loss was 3.1 g (range 0–9 g) during a 24-hour pad test. Versi et al. [72] studied 24 young continent women during a 48-hour pad test and reported a mean loss of 7.1 g, with a 95% upper confidence limit of 14.5 g. Mouritsen et al. [76] reported a mean leakage of 2.6 gm in continent women during a 24-hour pad test, with a 95% upper confidence limit of 5.5 g. In a more recent study, an upper limit of 1.3 g/24 hours was noted [77]. Although only supported by the latter study, the committee on Imaging and Other Investigations from the second International Consultation on Incontinence [67] recommend that a pad gain of ≥ 1.3 g during a 24-hour pad test be considered as positive.

Validity and Reliability

The construct and convergent validity of home pad test, i.e., its ability to not record weight gain in continent women and its ability to detect urine loss in patients with established urinary incontinence on UDS, has been reported. Using continent volunteers, Molloy et al. [73] noted the weight gain of up to ±1.3 cc for each 12-hour periods, likely representing vaginal discharge. One study failed to confirm construct validity, with continent and incontinent women showing no difference in pad weight gain [75]. More recently, it was noted that there was little [78] or no [79] correlation between a 24-hour pad test and a cough stress test.

Convergent validity showed moderate or weak correlation between a 24-hour pad test and the severity index [80], the quality of life questionnaire (Incontinence Impact Questionnaire) [78], and the symptom questionnaire (Urogenital Distress Inventory) [78] but high correlation with a complaint of stress incontinence [70] and the number of incontinence frequency as recorded on diary [81,82] and on ICIQ-SF questionnaire [82]. No correlation with Stamey grade was noted [82]. The 48-hour pad test correlated moderately with the Urinary Incontinence Severity Score and strongly with a visual analogue scale quantifying bothersomeness of current incontinence [83].

Convergent validity with UDS was assessed in numerous studies. Some concluded that the 24-hour pad test is perhaps more sensitive than v-UDS [72,84]. The false negativity of the 24-hour pad test has been estimated to be around 8% [72]. These earlier studies suggest a reasonably low false-negative 24-hour pad test compared to UDS and an improved detection of urinary incontinence in symptomatic subjects with negative UDS. This is in contrast with later study in which 33% of women with urodynamic stress incontinence, 43% of those with detrusor overactivity, and 37% of women with missed UDS diagnoses were dry on the 24-hour pad test [15]. The amount lost on 24-hour pad test is not discriminatory of urodynamic diagnosis [15]. Furthermore, the 24-hour pad correlates negatively only very weakly with the vesical leak point pressure [81].

The long pad tests have a good test–retest reliability as shown by the correlation obtained, keeping in mind the limitations of the ability of this measure of association in determining agreement. Victor et al. were the first to compare test–retest of the 24-hour pad test [85]. A 48-hour pad test was performed by 15 women and repeated it 1 week later. When comparing the first 24 hours of the two 48-hour pad tests, correlation was significant ($r = 0.66$). Lose et al. [70] performed test–retest evaluation of the 24-hour home pad test in 31 women referred for incontinence. A significant correlation ($r = 0.82$) was noted between the two tests. The limit of agreement was approximately ±100 g, which means that the second test done could yield greater or lesser results the second time by as much as 100 g. This represents a large variability of results. Rasmussen et al. [86] evaluated 14 women for test–retest reliability of the 24-hour pad test. They failed to find a linear correlation between the two tests. The second test could be anywhere between a third less to three times more than the first 24-hour period tested. Versi et al. [72] looked at the reproducibility of the first 24 hours from a 48-hour pad test compared to the first 24 hours of a second 48-hour pad test in 140 symptomatic patients. They noted a strong correlation (0.9) and a difference between the two tests of 7%. When looking at the test–retest done during the first 24 hours of a 72-hour pad test done twice in 106 women, Groutz et al. [87] used another statistical marker of reliability (Lin's concordance correlation coefficient [88], in which reliability was defined as a coefficient > 0.7). The coefficient obtained was 0.72. More recently, Karantanis et al. [89] assessed the repeatability of 7 consecutive 24-hour pad tests on 108 women using repeated measures ANOVA. No difference in mean pad test among the 7 days was detected, suggesting repeatability.

Similarly, the test–retest reliability of the 48- and 72-hour pad test has been reported to be very good, although the statistic used (correlation) are of limited strength to measure association. Victor et al. [85] reported a correlation coefficient of 0.9 between two tests at least 1 week apart. Versi et al. [72] reported similar correlation, with a difference in weight between the two tests of only 1.6%. Groutz et al. [87], when comparing the first 2 days of a 72-hour pad test done on two different occasion, found a concordance correlation coefficient (Lin's CCC) of 0.88. The test–retest correlation (using Lin's concordance correlation coefficient) was at the greatest for the 72-hour pad test (CCC = 0.94). The first 24 hours of a 48-hour pad test has been compared to the full 48-hour test and the two tests have been shown to highly correlate ($r = 0.92$), suggesting that the 48 hour did not add much to a 24-hour test [90]. More recently, Karantanis et al. [89] reported high correlation ($r = 0.88$) between the first 24-hour pad test and the 7-day average of 7 consecutive 24-hour pad tests.

Attempts at categorizing severity of incontinence according to weight gain on long pad test were done by applying the percentage of the data that were classified as mild, moderate, or severe on the 1-hour tests. Leak < 20 g on a 24-hour pad test was classified as mild, 20–74 g as moderate, and ≥75 g as severe [91]. Here also, no validity study has been done to assess agreement of this categorization with other measures of incontinence severity.

Attention must be given to local climate, as a test performed in a warmer, more humid climate leads to a higher pad humidity (1.9 g) than normative data supported by the ICS [67], as shown by testing 257 continent women [92].

A balance between the desired response rate and accuracy of the method must be struck, as the need to perform a 24-hour pad test had been shown to deter patient's participation in trial [56]. The committee on Imaging and Other Investigations from the fifth International Consultation on Incontinence [67] concluded that the 24-hour pad test was reproducible and recommended that a test lasting more than 24-hour had little advantage. It has been suggested that the 24-hour pad testing should be used as a composite outcome measure in research along with a 24-hour diary and a satisfaction questionnaire, as it was noted to reflect surgical results more accurately [93].

SHORT- VERSUS LONG-DURATION PAD TESTING

Overall, the home pad tests (24- or 48-hour) correlate poorly with 1-hour pad tests and are more sensitive than the shorter 1-hour pad test.

Ali et al. [69] first compared in an abstract the 1-hour to a 12-hour pad test, and they noted a "close correlation." In another study [70,95], 31 women with urinary incontinence who had a 1-hour pad test (standard volume of 200–300 mL) and a 24-hour pad test were studied. Of these, 13 had a negative 1-hour pad test, of which, however, 10 had a positive 24-hour pad test, giving a false-negative rate of 39% for the 1-hour pad test, compared to the 24-hour. No correlation was found between the 1-hour and the 24-hour. This report was echoed by others [84,85,90]. More recent studies have found a moderate-to-strong correlation between the 24-hour and the 1-hour tests, in addition to reporting that the 1-hour detected more incontinent women than the 24-hour [15,38].

Both tests lack the ability to discriminate between possible UDS diagnoses as there is considerable overlap between pad losses across the UDS diagnoses [15].

PAPER TOWEL TEST

Most of the methods objectively quantifying urine loss preclude detection of small volumes, as these may overlap with perspiration and vaginal secretions. A simple noninvasive test was developed to detect such losses associated with stress incontinence [96]. While a trifold brown paper towel is held under the perineum, the patient is asked to cough three times consecutively. The surface of the wetted area is calculated using the ellipse formula (πxy), x and y being the orthogonal axes of the area, and then converted to volume of urine lost (using a standard curve). The relationship between the measured area and a known fluid volume was found to have a very strong correlation ($r = 0.998$). In a test–retest evaluation within the same visit and between visits the authors also showed a high correlation coefficient and concluded that the quantitative paper towel test was accurate and reliable in detecting small losses of urine due to stress incontinence. The paper towel test has not been found to correlate with self-reported severity of incontinence [97]. Test–retest reproducibility was within 1 cc [98]. This test has not been validated against a gold standard diagnostic method such as multichannel v-UDS.

SUMMARY

To date, the objective urine loss test most useful in clinical practice remains to be the perineal pad test. A short version has been standardized to a certain degree by the ICS, rendering its use more uniform for research data collection. However, the bladder volume at the beginning of the 1 hr test should be standardized. The 1-hour pad test has not been found to have good reproducibility, though it is improved with standardized bladder volume. The short-term pad test was found to be valid in differentiating normal from abnormal continence mechanisms; however, its validity is somewhat limited as it has a significant false-negative rate. Finally, the ability of the short-term pad test (≤1-hour) to categorize severity of incontinence was noted to be poor.

The long-term pad test (≥24 hours), on the other hand, is valid in detecting incontinence, with a good sensitivity and a lower false-negative rate. The reproducibility was similarly noted to be good for both a 48-hour and a 24-hour test period. Hence, a 24-hour home pad test represents a good tool in detecting and quantifying incontinence. Neither test can distinguish between different types of urodynamic diagnosis.

ACKNOWLEDGMENT

I acknowledge the contribution of Dr. Eboo Versi, coauthor of this chapter in the first edition of this book.

31 Basic Urodynamic Tests: Uroflowmetry

Matthias Oelke

INTRODUCTION

Urodynamic observations (e.g., measurement of urinary flow) have been defined by the joint committee of the International Urogynecological Association (IUGA)/International Continence Society (ICS) to be observations made during urodynamic studies [1]. A particular urodynamic observation (e.g., decreased urinary flow rate) can have a variety of underlying causes and, therefore, is unsuitable to make a definitive diagnosis concerning a disease or condition. Hence, free uroflowmetry (spontaneous or no-catheter uroflowmetry) should never be used as a single test but always combined with clinical information (e.g., history, physical examination, frequency-voiding chart, or pad test) and other tests (e.g., measurement of postvoid residual urine, ultrasound assessment of the lower or upper urinary tract) to draw useful conclusions with regard to diagnosis or treatment benefit. Urodynamic observations may occur in the absence or presence of symptoms and signs.

Abrams regarded uroflowmetry as a screening test that should be performed as an essential examination prior to all other urodynamic testing and as a routine examination for the pre- and postoperative assessment of lower urinary tract dysfunction (LUTD) [2]. The report of the ICS Standardization Committee on Good Urodynamic Practices (2002) confirms this postulate [3]. The French Committee of Female Urology and Urogynecology (2007) recommends evaluation of bladder emptying by uroflowmetry and measurement of postvoid residual urine in all patients prior to surgery [4]. In women with urinary incontinence, the current version of the European Association of Urology (EAU) Guidelines on Urinary Incontinence (2012) does not mention uroflowmetry anymore [5]. However, the previous version of the EAU Guidelines (2009) considered uroflowmetry useful in incontinent patients who have “complicated” incontinence that includes—besides others—recurrent urinary tract infections, reported voiding dysfunction, significant pelvic organ prolapse, failed previous incontinence surgery, and after radiotherapy or pelvic surgery.

This chapter deals with the urodynamic observation of urinary flow. Such measurement objectively determines the volume of urine expelled from the bladder per time sequence and quantifies micturition. Moreover, if this volume–time equation is drawn as a curve, the measurement of urinary flow also gives information on how urine evacuation exactly proceeds. Objective and quantitative data, which primarily help in the understanding of voiding symptoms, are provided by measurement of urinary flow. As with all investigations, the diagnostic value of uroflowmetry depends on the way the test is performed, the quality of the measuring equipment, and the knowledge of the individual who interprets the measurement. This chapter provides information accordingly.

SYMPTOMS RELATED TO URINARY FLOW

Uroflowmetry aims to reproduce, qualify, and quantify urinary symptoms that have brought women to consultation or patients reported about during systematic assessment. However, uroflowmetry can only objectively investigate symptoms related to voiding but cannot explain symptoms related to urinary storage. Additionally, uroflowmetry cannot qualify or quantify voiding in women with urinary retention. In daily life, the individual is usually the only observer of her urinary flow, and the interpretation of subjective observations may need to be objectively confirmed and quantified by flow measurements. There may appear a discrepancy between subjective reporting and objective findings of urinary flow. Long or everlasting uroflow abnormalities might not be realized as abnormal because a comparison with normal voiding is lacking in those individuals. Furthermore, most women void in privacy and have little opportunity to compare voiding patterns [6].

The following urinary symptoms are related to voiding and have been defined by the joint IUGA/ICS Standardization Committee on Terminology of pelvic floor dysfunction in the year 2010 [1]:

- *Hesitancy* is the complaint of a delay in initiating micturition (i.e., difficulty in initiating micturition resulting in a delay in the onset of voiding after the individual is ready to pass urine).
- *Slow stream* is the complaint of a urinary stream perceived as slower compared to previous voids or in comparison to others.
- *Intermittency* is the complaint of urine flow that stops and starts on one or more occasions during voiding. In contrast, continuous flow is when the individual reports emptying the bladder without pauses during a single voiding attempt.
- *Straining to void* describes the complaint of the need to make an intensive effort (by abdominal straining, Valsalva or suprapubic pressure) to either initiate, maintain, or improve the urinary stream.
- *Spraying (splitting) of the urine stream* is the complaint that the urine passage is a spray of split rather than a single discrete stream (i.e., when urine flows to different directions).
- *Position-dependent micturition* is the complaint of having to take specific positions to be able to micturate spontaneously or to improve bladder emptying, for example, leaning forward or backward on the toilet seat or voiding in the semistanding position.
- *The need to immediately revoid* is the complaint that further micturition is necessary soon after passing urine.
- *Retention (urinary)* is the complaint of the inability to pass urine despite persistent effort (i.e., inability to void despite having a full bladder).

UROFLOWMETRY EQUIPMENT

The first documented urine flow measurement was performed by Eugen Rehfisch in Berlin, Germany, in 1897 using a flowmeter based on air displacement [7]. Historically, many different types of uroflowmeters were proposed. Some were based on the principle of voiding distance [8,9], audio [10], weight [11], variations of a constant magnetic field [12], rotating disk, measurement of size and velocity of drops [13], and air displacement [14]. Susset et al. [15] compared weight, rotating disk, and air displacement techniques and found that all of them have certain values and limitations. Gammie et al. [16] described the most commonly used uroflowmeters employing one of the following methods:

- *The gravimetric method*: This technique operates by measuring the weight of the collected fluid or hydrostatic pressure at the base of the collecting cylinder. In both cases, the output signal is proportional to the collected fluid mass. Gravimetric meters therefore measure accumulated mass, and mass flow rate is obtained by differentiation. Nowadays, most of the uroflowmeters use this principle of uroflow measurement that is considered as the most precise measurement technique.
- *The electronic dipstick method*: The electrical capacitance of a dipstick mounted in the collecting chamber changes as urine accumulates. The output signal is proportional to the accumulated volume and the volumetric flow rate is obtained by differentiation.
- *The rotating disk method*: The voided fluid is directed onto a rotating disk, thereby increasing the inertia of the disk. The power required to keep the disk rotating at a constant speed is proportional to the mass flow rate of the fluid. The accumulated mass is obtained by integration.

The accuracy of uroflowmeters was discussed in the ICS Good Urodynamic Practices Report [3]. There are differences in accuracy and precision of the flow rate signals that are dependent on the type of the uroflowmeter, internal signal processing, the proper use, and calibration of the flowmeter. The desired and actual accuracy of uroflowmetry should be assessed in relation to the potential information that could be obtained from the measurement of urinary stream compared to the information actually abstracted for clinical and research purposes. Some relevant aspects of the physiological and physical information contained in the urinary stream are outlined in the report.

The desired clinical accuracy may differ from the technical accuracy. The ICS report on Good Urodynamic Practices [3] recommends as standards a range of 0–50 mL/s for maximum urinary flow rate (Q_{max}), 0–1000mL for voided volume, maximum ±5% relative to full scale. As most uroflowmeters are mass flowmeters using the gravimetric method, variations in the specific gravity of the fluid have a direct influence on the measured flow rate. For example, urine of high concentration increases apparent flow rate by up to 3%. With x-ray medium, the flow rate may be overestimated by as much as 10%. Correction by calibration software is possible but seldom performed.

Since the overall accuracy of flow rate signals is not better than ±5%, it is not important to report Q_{max} to a resolution better than a full milliliter per second. A better resolution is possible under carefully controlled research conditions but such advanced measurement accuracy is usually not required in daily clinical practice, especially when screening for LUTD.

UROFLOW MEASUREMENT

Normal voiding occurs when the bladder outlet (urethra and internal and external urethral sphincters) completely relaxes and the detrusor actively contracts. The mechanical properties of a relaxed bladder outlet are usually constant, and the properties can be defined by the relationship between the cross-sectional area of the urethral lumen and the intraurethral pressure at the flow controlling zone. Below the minimum urethral opening pressure, the urethral lumen is closed and urine remains in the bladder; the lumen then widely opens with little additional pressure increase and urinary flow starts to emerge. The interpretation of uroflow curves can be performed by measuring several parameters and by gross interpretation of the flow curve itself.

PARAMETERS OF UROFLOWMETRY [1] (FIGURE 31.1A AND B)

- *Flow time* is the time over which measurable flow actually occurs. Flow time is expressed in seconds (s).
- *Voiding time* is the total duration of micturition, including interruptions. When voiding is completed without interruption, voiding time is equal to flow time. Voiding time is expressed in seconds.
- *Voided volume* is the total expelled volume via the urethra and expressed in milliliters (mL).
- *Flow rate* is defined as the volume of expelled fluid via the urethra per time unit and expressed in milliliters per second (mL/s).
- *Maximum flow rate* (Q_{max}) is the maximum measured value of the flow rate after correction for artifacts and expressed in mL/s.
- *Time to maximum flow* is the elapsed time from onset of flow to Q_{max} and expressed in seconds.
- *Average flow rate* (Q_{ave}) is voided volume divided by flow time, expressed in mL/s. The average flow should be interpreted with caution if the flow is interrupted or there is terminal dribbling.

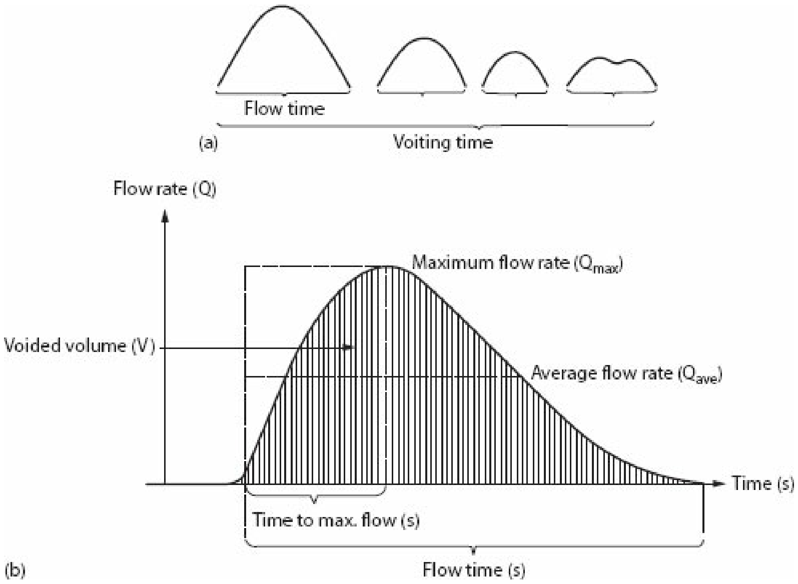

Figure 31.1 (a)Difference between flow time and voiding time. (b) Schematic explanation of uroflow recording, with nomenclature and units recommended by the International Urogynecological Association and International Continence Society. (From Haylen BT et al., *Neurourol Urodyn*, 29, 4, 2010.)

SHAPE OF THE FLOW CURVE

The shape of the flow curve is determined by the contractile properties of the detrusor, the ability to relax the bladder outlet, and the absence/presence of abdominal straining during voiding [1]. The ICS Good Urodynamic Practices Guidelines [3] state that an easily distensible, relaxed bladder outlet together with a normal detrusor contraction will result in a smooth, arc-shaped curve with high amplitude (Figures 31.1 and 31.2). When the bladder outlet is completely relaxed and the woman voids without straining, the shape of the curve is only determined by the kinetics of the detrusor contraction that reflects the properties of slow contracting detrusor smooth muscle cells; therefore, flow rate should not have rapid variations. The continuous uroflow curve is defined either as a smooth arc-shaped curve or as fluctuating when there are multiple peaks during a period of continuous urine flow (Figure 31.3). It is a widespread assumption that micturition of a healthy, asymptomatic woman is always associated with a normal flow pattern. However, this would also mean that a normal flow curve would correspond with normal voiding and would even permit the exclusion of LUTD. Pauwels et al. [17] demonstrated that a "normal" bell-shaped flow curve does not exclude female voiding dysfunction by investigating the value of a normal flow pattern in women with stress urinary incontinence (SUI), detrusor overactivity, healthy middle-aged volunteers, and healthy young students. These women voided with a bell-shaped flow curve in 50%, 65%, 57%, and 50%, respectively. Women who strained during voiding (a major component of dysfunctional voiding) managed to void a bell-shaped flow curve in 46%, 60%, 70%, and 100%, respectively.

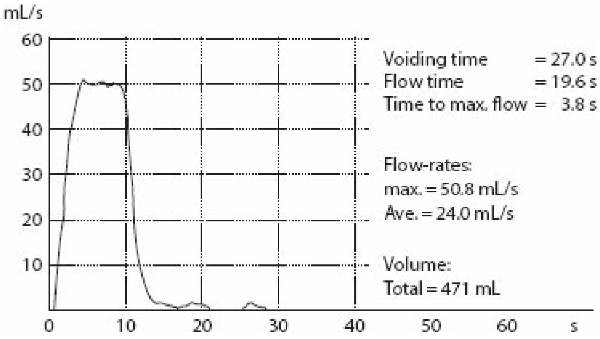

Figure 31.2 Bell-shaped uroflow with normal flow values.

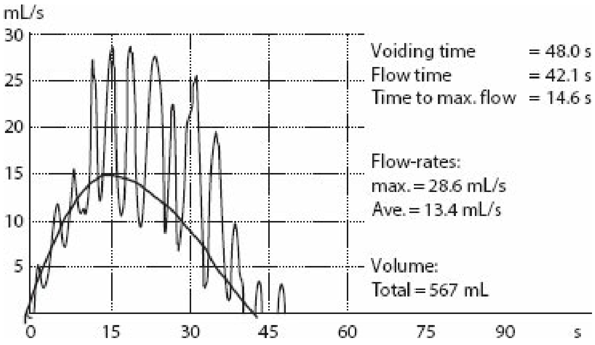

Figure 31.3 Fluctuating flow curve with multiple peaks, prolonged flow time, and normal maximum urinary flow rate (Q_{max}) during automatic evaluation but decreased Q_{max} after correction (straight arc drawn in flow recording). Flow curve possibly due to straining.

Other shapes of flow curves, such as flat (Figure 31.4), asymmetric, or multiple interrupted curves (Figure 31.5), are indicative of abnormal voiding but not specific for a certain underlying disease or condition. Decrease of detrusor contraction power (detrusor underactivity) and/or increased urethral pressure will both result in decreased Q_{max} and Q_{ave} as well as a smooth, flat curve. Constrictive obstruction, e.g., due to urethral strictures, meatal stenosis, or perforated vaginal tapes, is caused by a reduced size of the urethral lumen and results in a plateau-like curve (Figure 31.4). The magnitude of Q_{max} is determined by the residual urethral diameter at the level of obstruction. However, the same pattern may also originate from detrusor underactivity.

Fluctuations in detrusor contractility, straining, or intermittent sphincter activity during voiding may result in complex flow patterns (Figures 31.3 and 31.5). Rapid changes in urinary flow rate may be due to sphincter/pelvic floor contractions, mechanical compression of the urethral lumen or interference at the meatus, or changes in the driving energy—as with straining. Rapid changes may also be due to artifacts caused by interference between the stream and the collecting device, movement of the stream across the surface of the funnel, or patient movements. If fast variations of urinary flow have been observed, patients should be asked whether this voiding pattern reflects normal voiding at home or they have strained or emptied their bladder next to the collecting device. A visual control with regard to urine remnants next to the flowmeter is useful in cases of suspected voiding next to the uroflowmeter.

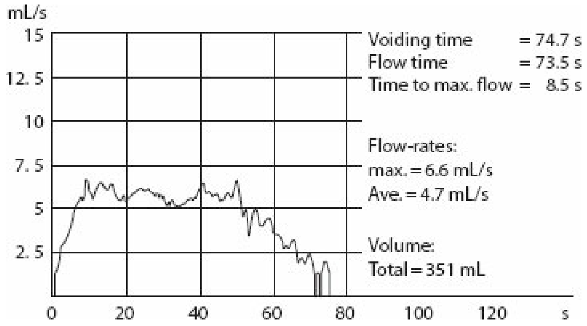

Figure 31.4 Flat flow curve with decreased maximum urinary flow rate (Q_{max}) and increased flow/voiding time, suspicious of bladder outlet obstruction, detrusor underactivity, or dysfunctional voiding

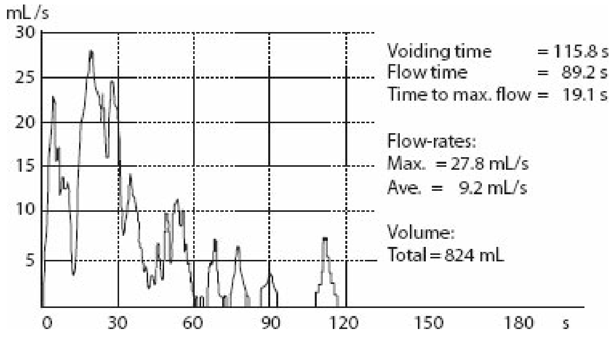

Figure 31.5 Multiple interrupted flow curve (staccatos) with normal maximum urinary flow rate (Q_{max}) but prolonged flow/voiding time, possibly due to straining, detrusor-sphincter dysfunction, or voiding next to the collecting device of the uroflowmeter.

INTERPRETATION OF UROFLOW VALUES AND CURVES [3]

As already mentioned, uroflow values and the shape of the flow curve may suggest LUTD but reliable, specific, and detailed information about the exact cause for abnormal voiding cannot be derived from uroflow (curve) alone [18]. Only measurement of the pressure–flow relationship by computer-urodynamic investigation can clarify the exact pathophysiology. Urine flow measurements are influenced by several factors that have to be taken into consideration during flow evaluation and interpretation. Not all relationships between voiding and specific conditions have been equally investigated in both men and women but are assumed to be similar in the context of this chapter:

- *Detrusor contraction power* (*contractility*): For steady outflow conditions and voiding without straining, all variations in urinary flow rate are only related to changes of detrusor activity and power. Detrusor contraction power can decrease with aging and in patients with neurogenic, myogenic, and combined diseases.
- *Bladder outflow resistance*: With changes of outflow resistance, for example, due to voluntary or involuntary urethral sphincter contractions during voiding or due to bladder outlet obstruction,

flow rate will change if detrusor contractility is constant. Q_{max} < 15 mL/s and/or postvoid residual urine volume >50 mL with a minimum total bladder volume of 150 mL before voiding (volume voided + postvoid residual) as well as the 10th centile curve of the Liverpool Nomogram for Q_{max} both correlate well with bladder outlet obstruction in women (Figure 31.6) [19].

- All *intra-abdominal pressure modulations* will result in physiological artifacts of the urinary flow rate and should be minimized, e.g., by asking the patient to relax and not to strain.
- *Patient age*: Healthy female volunteers aged between 16 and 64 years showed no statistically significant variation in urinary flow rate with regard to age, parity, or first vs. repeated voiding [20]. In female patients aged 40 years or older, Madersbacher et al. [21] described decreasing urinary flow rates (Q_{max},Q_{ave}) and increasing postvoid residuals with aging, indicating that older individuals have reduced bladder contraction power (detrusor underactivity) and/or a less compliant urethra. Additionally, bladder capacity, voided volume, functional urethral length, and maximum urethral closure pressure significantly decrease with increasing age. Deterioration of Q_{max} with aging was also described by Barapatre et al. in 308 healthy women aged 13–47 years [22]. A nomogram was developed to correct Q_{max} for age (Postgraduate Institute of Medical Education and Research, Chandigarh, India (PGIMER)—nomogram) [22].

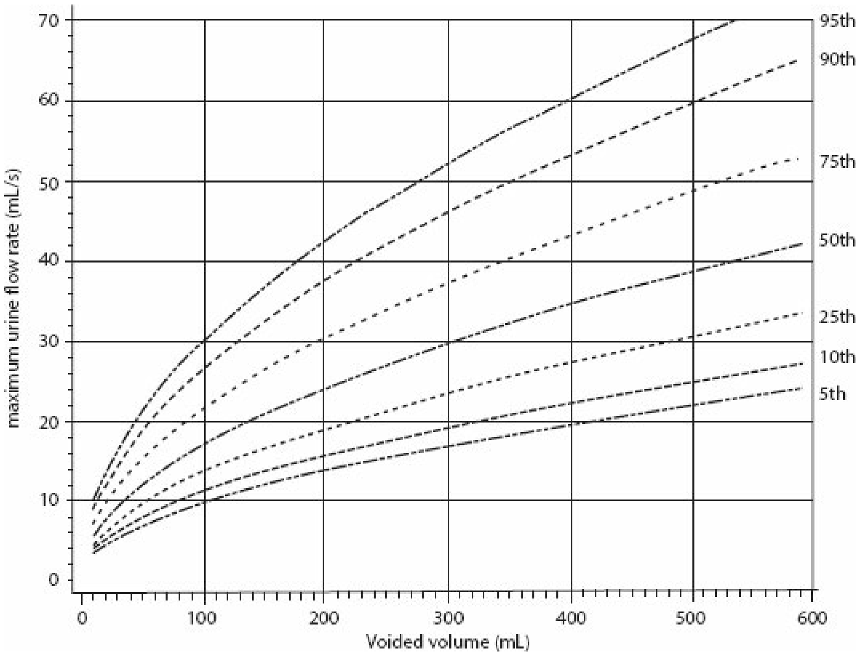

Figure 31.6 Liverpool Nomogram for the judgment of maximum urinary flow rate (Q_{max}) relative to voided volume in women. The patient has an abnormally low Q_{max} when the flow value relative to voided volume is under the 10th centile; these women should be further evaluated. (From Haylen BT et al., *Br J Urol*, 64, 30, 1989.)

- *Weight/body mass index*: A significant positive correlation between Q_{max} and body weight, body mass index, and body surface area has only been described recently [22]. Higher vesical resting pressures in the supine, sitting, and standing positions may be responsible for this positive association between Q_{max} and weight/body mass index [23]. This relationship could explain why Indian women have lower uroflow rates (Q_{max}) compared to women of western societies (Table 31.1).
- The *influence of urethral manipulation* on uroflowmetry results remains controversial. One study in women showed no difference between pre- and postcatheterization flow rates [24]. However, catheterization to rapidly fill the bladder in order to perform quick uroflowmetry can alter the following flow parameters: Q_{max} and Q_{ave} can decrease and time to Q_{max} as well as

duration of flow can increase [25–27]. Especially, catheters with a diameter of ≥7 French are likely to alter urine flow [28]. Although the effect of cystoscopy on urine flow parameters has only been evaluated in men, Issa et al. [29] demonstrated that Q_{max} significantly decrease by 27% after instrumentation. Therefore, urethral manipulation should be avoided prior to uroflowmetry whenever possible.

- Oral or intravenous *diuretics* as well as increased fluid intake can significantly reduce waiting time for urine flow measurement but do not significantly alter uroflow parameters such as Q_{max} or voided volume [30–32]. Although uroflowmetry is a noninvasive test suggesting no morbidity, excessive fluid intake has been associated with water intoxication resulting in hyponatremia and seizure [33].
- *Patient behavior and nervousness* during flow testing in the office may lead to incomplete sphincter relaxation and decreased urinary flow rates or even intermittent flow. Therefore, repeated uroflowmetry measurements should be carried out in women with altered flow parameters.
- *Circadian rhythm*: It was shown in men that urine flow varies during the 24 hour period with higher Q_{max} values, smaller voided volumes, and reduced flow time in the early afternoon when compared with the late evening, early morning, and midnight to morning periods [34]. Equivalent studies have not as yet been reported in women.

Table 31.1 Normal Uroflowmetry Values in Healthy, Symptom- and Disease-Free, Young to Middle-Aged Women Who Voided with a Comfortably Full Bladder

	Wyndaele [50]	**Pauwels et al. [37]**	**Oelke et al. [51]**	**Barapatre et al. [22]**
Population	10 healthy women	32 healthy women	30 healthy women	308 healthy women
Country	Belgium	Belgium	Germany	India
Voiding position	Sitting	Sitting	Sitting	Squatting
Age (years)	24	49 ±6	26.2 ±7.3	33.7 ±8.9
Range	19–28	38–60	16–40	13–47
Voided volume (mL)	338 ±234	340 ±165	492 ±175	291 ±167
Q_{max} (mL/s)	31 ±11	29 ±12	33 ±12	23 ±9
Q_{ave} (mL/s)	22 ±14	18 ±8	19 ±9	13 ±6
Time to Q_{max} (s)	8.3 ±8.1	7 ±3	10 ±5	8 ±6
Voiding time (s)	7.6 ±22	23 ±12	32 ±15	22 ±12
Flow time (s)	26 ±20	20 ±9	30 ±17	Not mentioned

*Note:*The values are given as mean ±standard deviation, unless otherwise indicated.

Q_{max}, maximum urinary flow rate; Q_{ave}, average urinary flow rate.

- *Influence of posture*: Devreese et al. [35] investigated the influence of three different postures on urine flow parameters in 21 healthy volunteers. Sitting in anteversion, retroversion, or forward bending, all without straining, showed no significant differences for Q_{max}, Q_{ave}, and total flow time. However, intermittent flow (staccatos) was less frequently seen in the forward-bending position, suggesting that this position permits optimal relaxation of the pelvic floor muscles and, therefore, is the most preferable voiding position. Nonadapted height of the toilet seat preventing the feet from resting on the floor or crouching over the toilet is associated with postvoid residual urine. In many Asian countries, women void in the squatting rather than in the sitting position; it was shown for Indian women that urinary flow rates were significantly lower (and postvoid residuals higher) in the sitting than in the squatting position [36].
- *Influence of straining*: A considerable proportion of healthy women strain to initiate or maintain voiding; in a prospective study of healthy, asymptomatic women, 42% strained during voiding [37]. Independent of the posture on the toilet, straining has been shown to increase Q_{max} and Q_{ave} and decrease total voiding time [35]. This reinforcement of flow occurs only when the urethra is completely relaxed and the flow controlling zone of the urethra is not under the influence of the abdominal pressure. Needle or surface electrodes did not show relevant

sphincter activity in healthy women who strained during voiding [37,38]. As discussed previously, straining can also produce a bell-shaped flow curve [17].

- *Bladder volume*: Q_{max} and Q_{ave} are physiologically dependent on bladder volume. A positive correlation has been found between bladder volume and Q_{max}/Q_{ave} (Figures 31.6 and 31.7) [20,39–41]. During bladder volume increase and progressive stretching of the detrusor, the potential bladder contraction power also increases. This is most pronounced in the range from an empty bladder up to approximately 200 mL of bladder filling. At bladder filling volumes higher than 400–500 mL, the detrusor becomes overstretched and contractility may decrease again; however, there are large interindividual differences [22]. The flow–bladder volume relationship also varies with the type and degree of pathology as, for example, in constrictive obstruction, where Q_{max} is almost independent of bladder volume.
- *Nomograms* were developed to correctly judge the relationship between voided volume and Q_{max} or Q_{ave} [40,41]. The Liverpool Nomogram gives the investigator quick advice about the volume-adjusted Q_{max} (Figure 31.6) or Q_{ave} (Figure 31.7) of the individual woman.
- *Free uroflowmetry vs. flow recording during pressure–flow studies*: It is necessary to insert a catheter into the bladder for vesical pressure recording; however, a transurethral catheter may interfere with voiding. Flow time is significantly increased and flow rates are significantly decreased in women with inserted urethral catheters compared to those without catheters, indicating that invasive uroflowmetry does not reflect physiological urination [27,28,42]. In women with invasive flow measurement, there were no differences between 4.5 and 6 F catheters, but significant differences between 4.5 and 7 F catheters. Furthermore, intermittent flow is more common with inserted catheters [27].

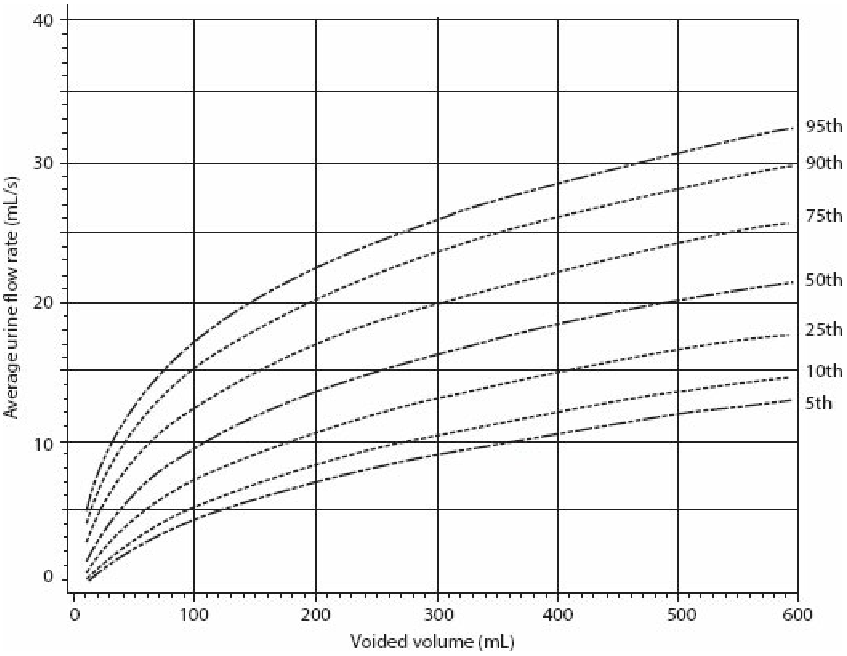

Figure 31.7 Liverpool Nomogram for the judgment of average urinary flow rate (Q_{ave}) relative to voided volume in women. (From Haylen BT et al., *Br J Urol*, 64, 30, 1989.) The patient has an abnormally low Q_{ave} when the flow value relative to voided volume is under the 10th centile; these women should be further evaluated.

- *Intraobserver variability* of measurements: Variability in interpretation proved relevant when done by 4 physicians with a minimum of 6 months of experience in urogynecology and with 8-week intervals between evaluations [18]. The difference was not large in the study by Jørgensen et al. [43] when the evaluation showed that visually read values were significantly lower than the mechanically determined ones, especially for Q_{max} in abnormal curves. The authors concluded that automatic computerized evaluation of uroflow curves may be misleading and cannot replace visual evaluation.

- *Interobserver variability* of measurements*:* Visual assessment of uroflow curves by urodynamicists demonstrated a substantial agreement of Q_{max}, Q_{ave}, flow time, voiding time, and the judgment of the curve as being "normal" or "abnormal" [44]. These results were independent of physicians' age or experience with uroflowmetry (<5, 5–10, or >10 years). Interestingly, there was a higher agreement between physicians who dedicated a relevant amount of their time to uroflowmetry compared to those who spent less than 5% of their working time on urodynamic practices. Computerized artifact detection and correction eliminates a relevant fraction of the variability of uroflow (Q_{max}) and decreases intra- and interobserver variability [45,46].
- *Home uroflowmetry* by means of a portable device proved to be a more accurate because it facilitates multiple measurements in a familiar environment [47,48]. A close relationship between Q_{max} at home and in the office was found, but voided volume was significantly larger and voiding time significantly longer in the office [47]. However, these variations between home and office flows appear to be irrelevant for screening of LUTD.

RECOMMENDATIONS FOR UROFLOW MEASUREMENT [3,4,49]

1. The flowmeter should be regularly calibrated and the calibration documented.
2. Patients should void with a "comfortably full bladder." Since this may be difficult to arrange in an office, patients should have the opportunity to drink fluids and void several times during one consultation.
3. Provide a separate room with clean material but without stimuli that might interfere with voiding (e.g., noise, music, disturbance, smell, dark atmosphere, or insufficient light). The flow curve should be recorded outside the flow room using electronic data transfer in order to avoid distraction during uroflow measurement.
4. Offer a toilet seat that allows the feet to rest on the floor.
5. After voiding in the office toilet, patients should be asked whether the void was representative compared to their usual voiding pattern at home. Additionally, patients should be asked whether they strained during uroflow measurement.
6. Compare the results of uroflowmetry with data obtained by the patient's own recordings on a frequency–volume chart (is voided volume in the office during uroflowmetry similar to voided volumes documented in the frequency-voiding chart?).
7. For graphical scaling of the flow curve, the x-axis represents time and 1 mm should equal 1 second. The y-axis represents the flow rate and 1 mm should equal 1 mL/s and 10 mL voided volume.
8. A sliding average over 2 seconds should be used to remove positive and negative spike artifacts in order to make electronically read Q_{max} values more reliable, comparable, and clinically useful.
9. Flow traces and the computer output derived form should be carefully scrutinized for artifacts and corrected, if necessary.
10. Only flow rate values smoothed either electronically or manually should be reported [40]. When reading Q_{max} graphically, the line should be smoothed by eye into a continuous curve so that, in each period of 2 seconds, there are no rapid changes (Figure 31.3).
11. Q_{max} should be rounded to the nearest whole number (e.g., a recorded value of 10.25 mL/s should be reported as 10 mL/s).
12. Voided volume and postvoid residuals should be rounded to the nearest 10 mL (e.g., a recorded value of 322 mL should be reported as 320 mL).
13. Q_{max} should always be documented together with voided volume and postvoid residual urine volume.
14. If a flow–volume nomogram is used, the name should be stated and referenced (e.g., Liverpool Nomogram, Figures 31.6 and 31.7).
15. Do more than one test, especially when the first flow does not permit a clear interpretation, has shown pathological values or an abnormal flow curve, or was reported not to be representative

compared to home flows.

16. Measurement of postvoid residual urine improves interpretation of the test.

UROFLOWMETRY IN HEALTHY VOLUNTEERS

For correct judgment of measurement values and curves and for adequate interpretation of uroflowmetry results, it is important to have data of age-matched healthy individuals. These normative data should derive from groups of healthy, symptom-free, and disease-free volunteers. Table 31.1 lists free uroflowmetry data of healthy asymptomatic volunteers who voided with a full bladder [22,37,50,51]. Normal Q_{max} depends on the voided volume and ranges between 12 and 40 mL/s [52]. When women void with a full bladder, mean Q_{max} is between 23 and 33 mL/s and mean Q_{ave} between 13 and 22 mL/s. Voiding time varies from 10–20 seconds at a volume of 100 mL to 25–35 seconds for a volume of 400 mL [53].

Arbitrary criteria have been proposed by a number of authors to diagnose LUTD. For bladder outlet obstruction, the equation of Q_{max} <15 mL/s and/or postvoid residual urine volume >50 mL in a bladder filled with a minimum of 150 mL before voiding (volume voided + postvoid residual) was suggested [19,54]. Costantini et al. [19] showed that these criteria correlated well with the results of the Liverpool Nomogram when voided volumes less than 15 mL and more than 600 mL were excluded. It was concluded that values below the 10th centile are abnormal (Figure 31.6).

Wyndaele [50] compared the uroflow curve in 10 young female volunteers and found 7 to have a bell-shaped curve on free flow, 1 voiding in two separate curves, and 2 presenting a continuous but undulating curve during the entire flow. When compared to the curve obtained during a subsequent pressure–flow study, 7 had the same pattern but 3, with bell-shaped curve during free uroflowmetry, had an irregular or interrupted flow pattern. Pauwels et al. [17] found that during free uroflowmetry only 83% of middle-aged healthy women and only 75% of young and healthy individuals voided with a normal voiding pattern. In uroflowmetry recorded during pressure–flow analysis, only half of the healthy women voided with a normal flow pattern. The flow patterns during free uroflow (without catheter) and pressure–flow recording (with catheter) corresponded in 47%–75%, respectively, depending on patients' symptoms. Free uroflow and pressure–flow patterns matched better in healthy women than in patients.

Miyata et al. [55] analyzed voiding parameters in 36 healthy adult females and found voiding time to be a useful parameter that was independent of the voided volume between 100 and 400 mL and never exceeded 21 s in all voiding attempts. Voiding time was shorter in healthy volunteers than in 84% of neurogenic patients and 67% of patients with chronic cystitis.

UROFLOWMETRY IN FEMALE PATIENTS

Several conditions may influence uroflow values and shapes and, therefore, should be taken into consideration before flow measurement and during interpretation of the flow curve. Voiding difficulties, defined as abnormally slow and incomplete voiding, have frequently not been reported by the affected women and are often only detected during systematic evaluation of voiding function. Therefore, a detailed voiding history and screening uroflowmetry are recommended in women at risk:

- *Pregnancy and puerperium*: A significant increase in uroflow rate was only seen in the second trimester of pregnancy [56]. A significant decrease of uroflow rate was documented during intravenous tocolysis with α-adrenoceptor agonists. Urinary flow rates were worse after forceps delivery but better after spontaneous delivery compared to controls; however, all flow rates remained within the normal range.
- *Delivery*: Comparison of urinary flow curves between primiparas and nulliparas showed no differences with regard to Q_{max}, Q_{ave}, voided volume, voiding time, and time to Q_{max} [35]. However, cesarean section seems to be more frequently associated with postvoid dribbling.
- *Menstrual cycle*: No differences were seen in any measured uroflowmetry parameter when comparing similar voids between different phases of the menstrual cycle. Therefore, when evaluating premenopausal patients, uroflowmetry may be scheduled and performed during any phase of the menstrual cycle [26].
- *SUI*: Conflicting data have been published with regard to Q_{max} in women with SUI. Bottaccini

and Gleason [57] contended that stress incontinent women void with a lower uroflow rate than healthy women because the distal urethral cross-sectional area appears to be incapable of opening as widely as the distal urethra of normal women. However, other studies have demonstrated the opposite: SUI women void with higher flow rates because of lower bladder outlet resistance [58]. Free uroflow appears to have a low positive predictive value for indicating abnormal pressure–flow studies in SUI women with or without previous surgery [59,60].

- *Genital prolapse*: Q_{max}, Q_{ave}, and voided volume have been described to be significantly lower than in healthy controls [48]. Cystocele appears significantly more frequent in patients with voiding difficulties and, vice versa, the frequency of cystocele and voiding dysfunctions was shown to be significantly higher in women with abnormal uroflowmetry [19]. Valentini et al. [61] demonstrated a constrictive effect on the bladder outflow in women with various degrees of cystocele. Poor uroflow rates and elevated postvoid residuals appear to be associated with higher grades of cystoceles [62].
- *Large uterine fibroids*: One study reported that Q_{max}, Q_{ave}, and voided volume are significantly lower in disease than in healthy controls [48].
- *Uroflowmetry in women before and after SUI surgery*: Normal or abnormal uroflow parameters before surgery, including Q_{max}, do not predict urinary retention after SUI surgery [63,64]. There is, however, some evidence that poor bladder emptying before surgery, defined as low flow rates and/or evidence of postvoid residuals, may predict voiding difficulties after SUI surgery [65,66]. Free uroflow at a follow-up of 1 year after tension-free vaginal tape (TVT) implantation showed —compared to preoperative values—a statistically significant decrease of Q_{max} and increase of postvoid residual urine [67]. By applying modeling of free uroflow, Fritel et al. [68] showed development of compressive obstruction in 34/50 patients (68%) after the TVT procedure. The counterpressure of the tape on the urethra results in continence. During voiding, this effect can be unmasked if women strain, resulting in lower flow rate. The hypothesis of constrictive obstruction with reduction of the cross section of the urethra of about 60% was proposed for 27 patients.
- *Radical hysterectomy for cervical cancer*: Compared to the preoperative situation, increased postvoid residuals and decreased uroflow rates were detected in women after radical hysterectomy [69]. Bladder dysfunction was attributed to a significant reduction of detrusor contraction power (contractility) with concomitant abdominal straining due to impaired parasympathetic motor innervation [70]. However, the values improved from baseline to 6 months after surgery.

CONCLUSIONS

Uroflowmetry is a valuable, cheap, noninvasive, and fairly reliable screening test for women with suspected LUTD. Practical application and interpretation of free uroflowmetry results have to follow strict rules. Uroflowmetry should always be combined with other clinical tests for the assessment of bladder function/dysfunction or screening of treatment. In patients with a pathological uroflow, additional pressure–flow studies are recommended to evaluate the exact cause of LUTD.

Basic Urodynamic Tests: Filling and Voiding Cystometry

Hashim Hashim and Paul Abrams

DEFINITION

Cystometry, a part of urodynamic studies, is the measurement of relevant physiological parameters taken during the filling and voiding phases of micturition, allowing direct assessment of lower urinary tract function [1]. It can be divided into two parts:

1. *Filling cystometry*: The method by which the relationship of pressure and volume in the bladder is measured during bladder filling.
2. *Pressure–flow studies of voiding*: The method by which the relationship of pressure in the bladder and urine flow rate is measured during bladder emptying.

AIMS

Cystometry is performed clinically as part of urodynamic investigations in patients complaining of lower urinary tract symptoms (LUTS) to help make a diagnosis and hence plan a suitable treatment or further appropriate investigations.

Cystometry aims to evaluate detrusor and urethral function during the storage (filling) and voiding phases of micturition. It is essential that diagnoses made at the time of cystometry are related to the patient's signs and symptoms and the physical findings at the time of examination. The aim is to reproduce the patient's symptoms and to quantify the pathophysiological processes, thus providing an explanation of the patient's problems and an understanding of their implications. Cystometry can also be used for research purposes or to provide objective measurements following particular treatments.

INDICATIONS

Ideally, all patients with LUTS suggesting a bladder or urethral disorder should undergo urodynamic studies. The bladder is known to be an "unreliable witness": urinary symptoms alone do not always allow the correct diagnosis to be made and inappropriate treatment may be given [2–6]. However, with limited health-care resources and access to such a service, patients with "clear-cut" symptoms can initially be managed empirically, for example, by pelvic floor exercises or with duloxetine (serotonin norepinephrine reuptake inhibitor), available in some parts of the world, for suspected stress urinary incontinence, and bladder training, antimuscarinics, and/or mirabegron for overactive bladder syndrome and suspected detrusor overactivity (DO).

Urodynamics should not be performed without clear indications and a proposed *urodynamics question(s)* that will be answered by the investigation [7]. Cystometry should be preceded by the completion of a 3-day frequency/volume chart or bladder diary, e.g., ICIQ-BD (Figure 32.1) [8], and free uroflowmetry. Ideally, two successive free flows are performed [9,10].

Urodynamic tests should be considered in women:

- With mixed LUTS in whom surgery is contemplated (e.g., urgency/urgency incontinence and stress urinary incontinence)
- With a suspected voiding disorder
- Being considered for bladder neck surgery
- With previous unsuccessful incontinence surgery
- With neurogenic bladder disorders
- Complex cases, e.g., prior to kidney transplant
- In whom conservative and pharmacologic measures have failed; for example, physiotherapy for symptoms of stress urinary incontinence and antimuscarinic drug treatment, mirabegron, and

bladder training for symptoms of overactive bladder syndrome

PREPARING FOR CYSTOMETRY

Quality Control during Cystometry

Quality control is vital to allow accurate, reproducible, and interpretable pressure readings and to allow identification of artifacts. The International Continence Society (ICS) has defined these steps in the 2002 Good Urodynamic Practices report [7]:

Flushing: The manometer tubing connecting the transducers must be flushed before setting zero to remove any air bubbles that could give low false pressure readings.

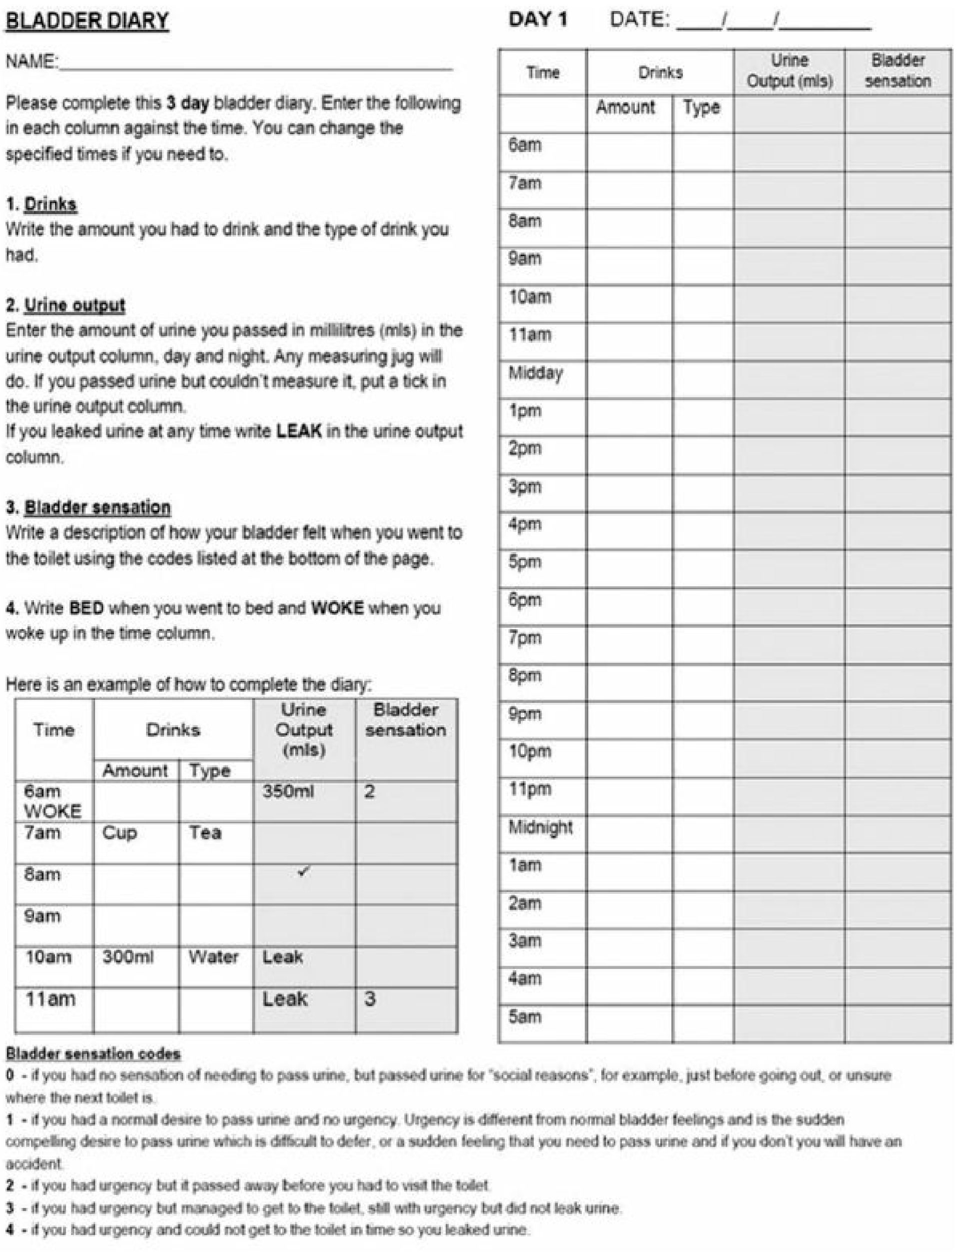
Setting zero at atmospheric pressure: This can be done either prior to inserting the catheters into the patient or after insertion as long as the transducers are open *only* to the atmosphere. Zero pressure is set when an external transducer is open only to the environment (the other two sides of a 3-way tap are closed) or when the open end of a connected, fluid-filled tube is at the same vertical level as the transducer before insertion into the patient (Figure 32.2).

Calibrating the transducers: They should be calibrated at 0 and +100 cmH_2O; the bladder (vesical) pressure (p_{ves}) and rectal or vaginal intra-abdominal pressure (p_{abd}) lines should be in the positive range +5 to +50 cmH_2O (depending on body position, lying or standing, and body habitus); the detrusor pressure (p_{det}) should be between –5 and +5 cmH_2O [11]. Neither the abdominal nor vesical pressure lines can be zero or negative as it is not possible to have these pressures physiologically. Detrusor pressure can be slightly negative as it is an artificial number from the subtraction of abdominal pressure from vesical pressure.

Establishing a reference level for pressure: The superior border of the symphysis pubis is the fixed reference level for external and fluid-filled catheter systems; the transducers should be levelled to this horizontal plane so that all measurements have the same hydrostatic component.

It is easier to add two 3-way taps to the pressure transducers, so that all procedures can be done by turning the valves alone without disconnecting any tubing and using syringes in a vertical position, maintaining connections, eliminating all air bubbles, and avoiding any new air bubbles (Figure 32.2).

During the investigation, quality control is ensured by asking the patient to cough at regular (e.g., 1 minute) intervals (Figure 32.3). Before recording is started, the patient is asked to cough and the p_{ves} and p_{abd} traces are observed. The two cough spikes should show an equal rise in the two pressure lines (p_{ves} and p_{abd}) and a complete subtraction of these two pressures should result in no change of the p_{det} line. Sometimes, a small artifactual biphasic blip (Figure 32.3) is seen on p_{det}, but this also indicates acceptable subtraction. The biphasic blip occurs due to different speeds of transmission of the pressure waves from the bladder and rectum/vagina to the two transducers and is seen mainly in older urodynamic systems. The two blips of the biphasic wave should be equal in size; if they are not equal in height, this can indicate poor quality. The patient should cough before and after voiding to reconfirm quality control and that no displacement of catheters has occurred. During filling, the p_{ves} and p_{abd} lines should not decline.



BLADDER DIARY

DAY 1 DATE: ____/____/________

NAME:____

Please complete this **3 day** bladder diary. Enter the following in each column against the time. You can change the specified times if you need to.

1. Drinks
Write the amount you had to drink and the type of drink you had.

2. Urine output
Enter the amount of urine you passed in millilitres (mls) in the urine output column, day and night. Any measuring jug will do. If you passed urine but couldn't measure it, put a tick in the urine output column.
If you leaked urine at any time write **LEAK** in the urine output column.

3. Bladder sensation
Write a description of how your bladder felt when you went to the toilet using the codes listed at the bottom of the page.

4. Write **BED** when you went to bed and **WOKE** when you woke up in the time column.

Here is an example of how to complete the diary:

Time	Drinks		Urine Output (mls)	Bladder sensation
	Amount	Type		
6am WOKE			350ml	2
7am	Cup	Tea		
8am			✓	
9am				
10am	300ml	Water	Leak	
11am			Leak	3

Time	Drinks		Urine Output (mls)	Bladder sensation

1am				
2am				
3am				
4am				
5am				

Bladder sensation codes

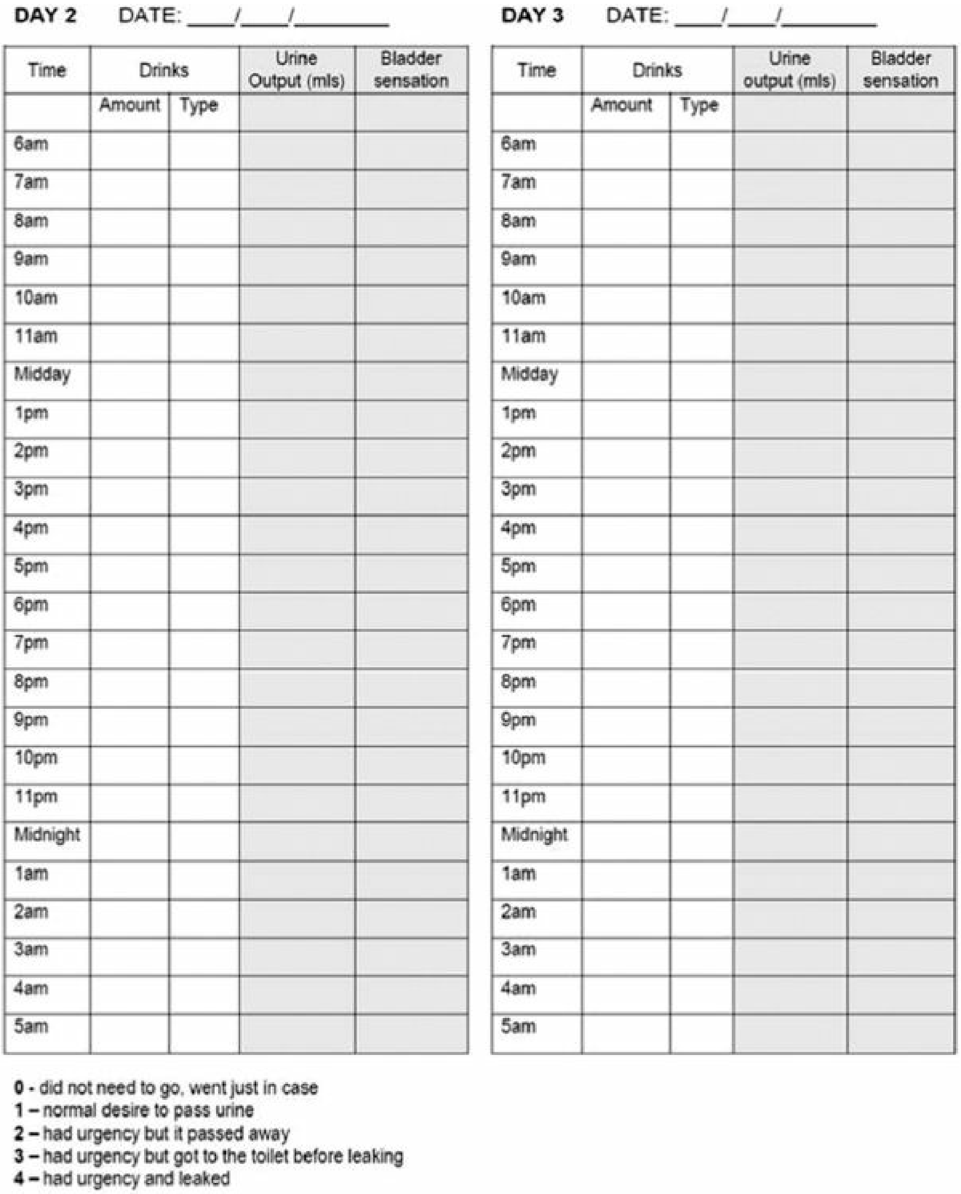
0 - if you had no sensation of needing to pass urine, but passed urine for "social reasons", for example, just before going out, or unsure where the next toilet is.

1 - if you had a normal desire to pass urine and no urgency. Urgency is different from normal bladder feelings and is the sudden compelling desire to pass urine which is difficult to defer, or a sudden feeling that you need to pass urine and if you don't you will have an accident.

2 - if you had urgency but it passed away before you had to visit the toilet.

3 - if you had urgency but managed to get to the toilet, still with urgency but did not leak urine.

4 - if you had urgency and could not get to the toilet in time so you leaked urine.



DAY 2 DATE: ____/____/________

Patient Position

For convenience, the catheters are put in position with the patient supine after the physical examination (Figure 32.4). Cystometry should then be done in the upright (sitting) position because (1) this is the physiological position in which women spend a substantial proportion of their time when awake, (2) the majority of women complain of symptoms when upright and active, and (3) at least 30% of DO will be missed if the patient is filled supine, resulting in suboptimal treatment decisions [12]. It is expedient to ask the patient to sit on a commode with a flowmeter situated below it to measure any leakage of urine during the test and also because most women void when sitting down. Some women complain of leakage when changing position (e.g., on bending over or getting up from the sitting position); these changes in posture can be mimicked during the test to try to reflect everyday stresses on the bladder and to reproduce leakage. Whenever the patient's position is altered, the position of the transducer must be readjusted to the pressure reference level of the upper border of the symphysis pubis.

With the catheters in position, the filling catheter is connected to a bag of suitable filling medium (see Figure 32.4). The rest of the equipment should be close to the patient for convenience, and if a computer screen is available, this should be in a position viewable by the patient so that explanations can be given during the test.

Figure 32.4 Catheter positions. The patient is in supine position only for catheter insertion.

If there is severe DO that prevents adequate filling, even at a reduced rate (10–20 mL/min), then filling in the supine position may be required in order for any useful information to be gathered from cystometry.

Reduced mobility or severely disabled patients (e.g., by neurological disease) may necessitate cystometry in the supine position.

Filling Medium

Water and 0.9% (normal) saline are the fluids most frequently used for bladder filling, as they are cheap, convenient, and mimic urine. The fluid is commonly used at room temperature (22°C); however, body temperature (37°C) may be more physiological. Cystometry has been performed with the filling medium warmed to body temperature with no observable difference in results [13]; however, this has not yet been scientifically investigated and standardization is required. It is known that ice-cold infusion fluid can stimulate bladder contraction at low bladder volumes [14] and therefore should not be used in routine cystometry.

In the past, carbon dioxide has been used in gas cystometry [15] but is no longer recommended as it is not a physiological medium for the bladder, it dissolves in urine to form irritant carbonic acid, and it can cause pain in “hypersensitive” bladders; furthermore, capacity measurement is inaccurate as the gas is both compressible and soluble in urine [16]. In addition, it is not possible to obtain a pressure–flow analysis of the voiding phase of micturition after gas cystometry.

Filling Rates

Previously, three filling rates were defined by the ICS [1]:

1. Slow-fill cystometry up to 10 mL/min
2. Medium-fill cystometry between 10 and 100 mL/min
3. Fast-fill cystometry when the rate is greater than 100 mL/min

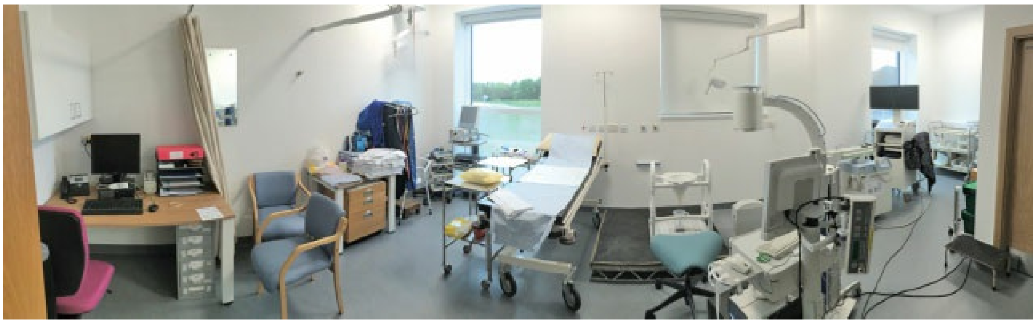

Figure 32.5 The equipment used are the couch, cystometry unit, patient unit, flowmeter—the image intensifier is used in videourodynamics.

In the latest standardization report, the ICS no longer divides filling rates into slow, medium, or fast. Currently, the term “nonphysiological filling rate” is used, and the precise filling rate should be stated. We recommend a filling rate of 50 mL/min, which, although convenient in the setting of a busy urodynamic unit, is not so fast as to be grossly nonphysiological; it also allows time to discuss symptoms with the patient and to assess whether those symptoms have been successfully reproduced. In a patient with very marked DO, the rate should be reduced to 30 mL/min or lower.

Slower filling rates (10 mL/min) are indicated in patients with neurogenic bladder dysfunction. There is little point in more rapid filling, and there is risk of artifactually affecting bladder compliance, although some believe it to be a further provocative test for DO.

Equipment

Multichannel cystometry requires a urine flowmeter, two (or three) transducers, an electronic subtraction unit to derive p_{det} ($p_{ves} - p_{abd}$), a recorder with a printout, and an amplifying unit (Figure 32.5). All pressure measurements are made in centimeters of water (cmH_2O).

The bladder pressure is measured using either

- A fluid-filled line (a double-lumen or single-lumen epidural-type catheter is inserted into the bladder and connected to an external pressure transducer; Figure 32.6).
- A solid microtip pressure transducer (a transducer is mounted on the tip of a solid 7 Fr catheter and hence is an internal pressure transducer system; Figure 32.7). This catheter-mounted transducer eliminates artifacts arising from the fluid-filled system, which needs to be connected to an external transducer.

Abdominal pressure is measured with a rectal (or occasionally vaginal) [17] catheter (6 Fr single-lumen manometer tubing covered with a small perforated balloon to prevent blockage by feces; the perforation ensures that flushing the balloon does not build up elastic pressure) that is inserted into the rectum to a distance approximately 10 cm above the anal margin (or into the vaginal fornix, if the vagina is used). If the patient has no rectum or vagina but a colostomy, then that can be used for the abdominal pressure measurement. This line is taped to the patient’s buttock close to the anal verge to prevent any slippage during the test. The tubing must be flushed from the transducer end before recording is commenced. Some commercial rectal catheters do not have a hole and thus the balloon continues to expand with repeat flushing, resulting in false rectal pressures. It is therefore advisable to make a small cut in the rectal balloon even if you are using a commercial rectal catheter (Figure 32.6). Making a hole in the rectal balloon is not in the ICS Good Urodynamic Practices report [7] and the report suggests filling the balloon to 10%–20% of its capacity. However, this is often difficult to gauge and the balloon could easily be filled more than that, causing error in measurement. Some companies produce double-lumen catheters for measuring rectal pressure to allow insertion of fluid and aspiration to remove all air bubbles. The use of these commercial catheters may not be economical in some centers, and therefore a cheaper way of measuring abdominal pressure, which offers very good results for measuring abdominal pressure through the rectum, is to use a 6 Fr filling catheter or feeding tube and cover the end of it with a fingerstall obtained from a nonsterile surgical rubber glove and taped securely, but ensuring that a small hole is made in fingerstall to allow expulsion of fluid during flushing.

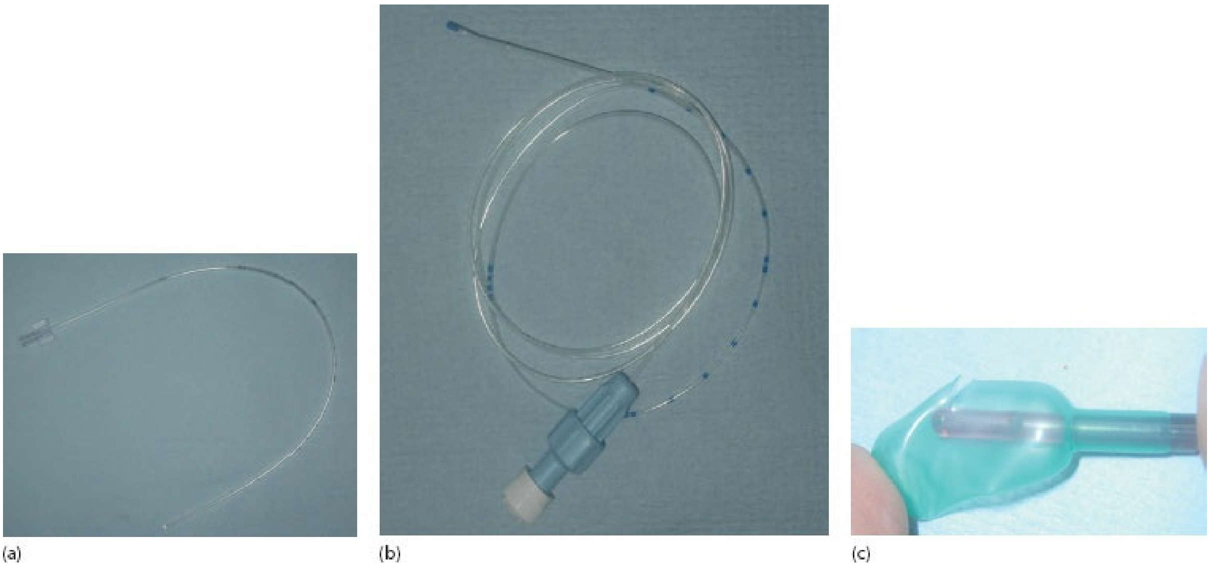

Figure 32.6 (a) Filling catheter (8 Fr), (b) epidural-type catheter (16G), and (c) rectal line with a hole made in balloon.

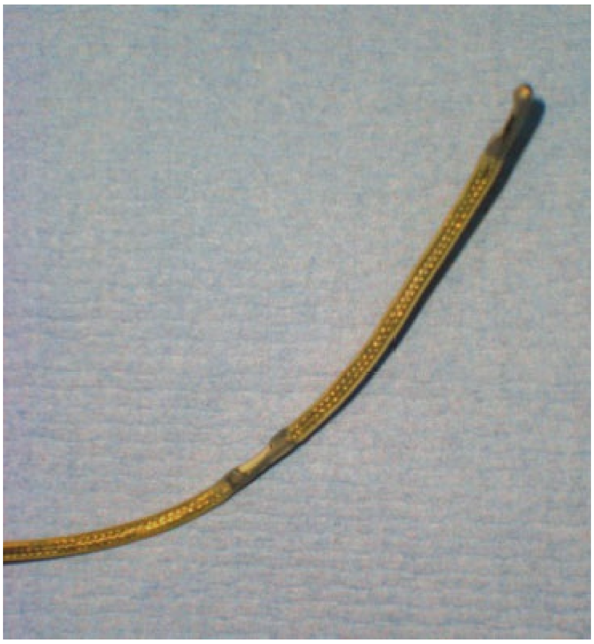

Figure 32.7 Solid catheter-tip transducer (Gaeltec).

The reference height for all measurements is taken as being level with the upper edge of the symphysis pubis and the transducers are zeroed to atmospheric pressure. A double-lumen filling catheter (6 Fr) is inserted into the bladder via the urethra (or, occasionally, by the suprapubic route). Sometimes a single-lumen (7 Fr) filling catheter with a 16G catheter for pressure measurement inserted alongside it can be used instead of the double-lumen [18]. 16G catheters are generally readily available in hospitals as they are commonly used for administration of epidural anesthesia. Double-lumen catheters are expensive and thus the two-catheter combination is a cheaper alternative that gives similar results. The single-lumen filling catheter is pulled out just before voiding and the 16G catheter is left in the bladder and used to measure pressure. The advantage of the double-lumen catheter is that the patient’s bladder can be filled and refilled multiple times should the test require it, and the postvoid residual (if any) can easily be drained and measured through it; however, it is more expensive to use.

The double-lumen catheters are also sometimes subject to more pump artifacts during filling (i.e., the small surges in pressure from the filling pump may transmit through the catheter to be detected by the pressure transducer). The catheters are fixed in place by tape close to the external urethral meatus on the medial aspect of the thigh.

Recently, air-filled catheters have been introduced to the market. However, it is important that those thinking of using air-filled catheters know that there has not been any standardization of technique or reference values produced, and it is not known whether the measurements made are equivalent to the fluid-filled catheters or not.

MEASUREMENTS

The following measurements are made (Figure 32.3):

- p_{ves} is measured via a urethral or suprapubic catheter connected to the bladder transducer.
- p_{abd} is the pressure within the abdomen, outside and around the bladder, and is measured in the rectum or vagina.
- p_{det} is obtained by subtracting the abdominal from the intravesical pressure ($p_{det} = p_{ves} - p_{abd}$) and represents the pressure generated by the bladder wall, usually as detrusor contractions.
- The volume infused into the bladder is recorded.
- The urine flow rate, as leakage during filling and flow during voiding, is recorded.

Measuring bladder and intra-abdominal pressure simultaneously ensures that any pressure changes observed can be interpreted correctly. A rise in the vesical pressure could be due to either DO or abdominal straining being transmitted to the bladder. The electronic subtraction allows detrusor pressure to be measured and any change in pressure seen on the traces to be attributed appropriately.

Detrusor function is assessed directly from observation of the pressure changes. Urethral function must be inferred from the pressure changes within the bladder and by measuring any leakage during filling and urine flow during voiding.

METHOD

The basic details of the test and the most frequent side effects (e.g., risk of urinary tract infection) should be fully explained to the patient, and, in particular, the importance of indicating any bladder sensations during the test, as they happen, should be emphasized. The symptoms can then be used to annotate the cystometry trace and help with interpretation.

Urinalysis and free uroflowmetry should be performed before embarking on cystometry to exclude any abnormality that may preclude proceeding with the test or may need extra precautions to be taken during the test, such as a urinary tract infection. Any residual urine on subsequent catheterization is then measured. We normally empty the bladder of any residual urine in nonneurogenic bladders, as this allows us to assess bladder function when the bladder is empty, which may be important if treatment involves emptying the bladder, such as when using intermittent self-catheterization.

Filling Cystometry

The filling phase starts when filling commences and ends when the patient is given permission to void by the urodynamicist. Bladder sensation, detrusor activity, bladder compliance, bladder capacity, and urethral function should all be assessed during this procedure. The degree of bladder filling should be guided by the voided volumes recorded on the bladder diary.

Bladder Sensation

During the filling phase, the patient is asked to indicate when and if the following occur:

- First sensation of bladder filling [1]: This is the feeling of first becoming aware of bladder filling. This sensation may not be truly representative, owing to the interfering presence of the catheter.
- First desire to void (FDV) [1]: This is the feeling that would lead to passing urine at the next convenient moment, but voiding can be delayed if necessary. Essentially this is the normal

desire to void in the old ICS terminology [19].

- Strong desire to void (SDV) [1]: This is the persistent desire to void, without the fear of leakage.
- Urgency [1]: This is the complaint of a sudden compelling desire to void, which is difficult to defer. It is an abnormal sensation, distinct from SDV.

The volumes should be noted. The aforementioned terminology has been defined by the ICS [1]. Other terms that are also used during filling cystometry and related to bladder sensation include first sensation of bladder filling, bladder pain, and bladder sensation—which can be categorized as increased, normal, reduced, absent, or nonspecific (seen mainly in neurological patients).

Bladder hypersensitivity is a term that has been used in the past and found to be helpful [13]. It is defined as a condition where there is an early FDV at less than 100 mL and this persists and worsens, limiting the bladder cystometric capacity to a maximum of 250 mL. This term has now been replaced with the term "increased bladder sensation," which is an early first sensation of bladder filling (or an early desire to void) and/or an early SDV, which occurs at low bladder volume and which persists. The new term is subjective and thus it is not possible to quantify volumes.

Detrusor Activity

Detrusor activity, during filling, is described as either "normal" or "overactive." A normal detrusor allows bladder filling with little or no change in pressure and with no involuntary phasic contractions occurring during cystometry, despite provocation [1].

The presence of involuntary phasic detrusor contractions, occurring throughout filling, is diagnosed by a rise in the detrusor pressure line (there is no lower limit for the amplitude of an involuntary detrusor contraction) with a similar pressure rise in the vesical line, but no fall in pressure in the abdominal line, during filling cystometry (Figure 32.8). The patient should be asked whether there is any associated sensation (urgency) and if the sensation mimics the one that is normally experienced and causes problems. Provocative factors such as coughing or running water maybe used to provoke symptoms, such as stress incontinence or urgency due to DO, and should be noted.

If the bladder is shown during cystometry to contract spontaneously or with provocation, then it is said to have phasic DO. Some women will not experience any symptoms at the time of these contractions, in which case the significance of DO is unknown. If a single involuntary detrusor contraction occurs at the end of filling, resulting in incontinence, with no overactivity during filling, then this is known as terminal DO.

When there is a known neurological condition (e.g., multiple sclerosis), any DO observed is termed neurogenic DO (this replaces the older term of detrusor hyperreflexia). DO is idiopathic if there is no identified cause.

Bladder Compliance

The term bladder compliance describes the relationship between change in bladder volume and detrusor pressure ($\Delta V/\Delta p_{det}$) and is measured in mL/cmH_2O. Normal compliance is at least 40 mL/cmH_2O. As a normal bladder fills, there is very little or no change in the pressure (i.e., the bladder is a high-compliance system). As filling rates can alter bladder compliance, the filling rate of cystometry must always be documented. In neurologically normal women, reduced compliance is usually artifactual owing to the bladder being filled excessively fast. Should compliance start to rise during filling, the filling should be stopped for approximately 1 minute to see if the compliance returns to normal: if compliance returns to normal, the increase is artifactual and secondary to fast filling; if compliance does not return to normal, then it is secondary to a pathological condition. Continued filling should be at a slower rate of not more than 20 mL/min.

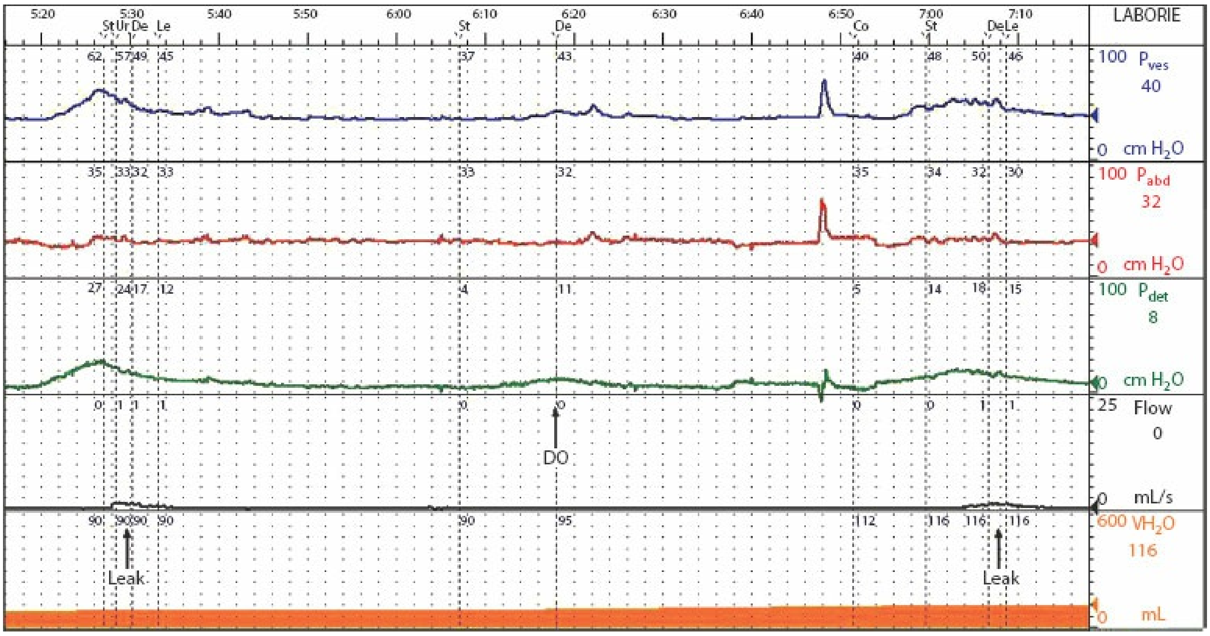

Figure 32.8 Cystometrogram showing detrusor overactivity (DO) and DO incontinence (leak). (p_{det}, detrusor pressure; p_{abd}, intra-abdominal pressure; p_{ves}, vesical pressure; flow rate in mL/s; V_{H2O}, volume of filling medium infused.)

Urethral Function

During the filling phase, in normal women, the urethral closure pressure ($p_{ura} - p_{ves}$) remains positive (i.e., urethral pressure is greater than the vesical pressure), even at times of increased abdominal pressure; hence, continence is maintained. To allow voiding, closure pressure falls to zero as the urethra relaxes. If involuntary loss of urine is observed without detrusor activity, then the urethral closure mechanism is said to be incompetent.

A diagnosis of urodynamic stress incontinence (USI) can be made if leakage is associated with an increase in intra-abdominal pressure that causes the vesical pressure to exceed the urethral pressure in the absence of a detrusor contraction (Figure 32.9). When filling volume reaches 200 mL, filling is stopped and the patient is asked to strain and then to cough to observe any leakage during these two maneuvers that tend to increase abdominal pressure above urethral pressure in women with the symptom of stress urinary incontinence. The intravesical pressure at which urine leakage occurs due to increased abdominal pressure in the absence of a detrusor contraction is known as the abdominal leak point pressure (ALPP) [1]. ALPP can be divided into cough leak point pressure and Valsalva leak point pressure (VLPP). If the patient leaks with a VLPP of less than 60 cmH_2O, then this is more indicative of USI secondary to intrinsic sphincter deficiency. If the VLPP is more than 90 cmH_2O, then the USI is more indicative of urethral hypermobility. These values are not “black and white” but can be used as a rough guide as to the cause of the stress incontinence, thus directing treatment options.

Filling is continued until the patient feels their bladder is full, at which point a cough is performed and permission to void is given.

Voiding Cystometry

At the end of filling, the bladder-filling catheter is removed (only if separate single-lumen filling and pressure catheters are used rather than a double-lumen catheter) to avoid any artifacts during voiding as a result of urethral obstruction. If leakage has not been noted during the filling phase, the patient is asked to cough a few times. If leakage is still not noted at this time, the patient is asked to stand and is given instructions on physical exertions to try to provoke leakage. Provocative maneuvers for DO incontinence include standing with the legs apart and running water from the taps and/or hand washing, whereas coughing, jumping (star jumps), and squatting are tests for USI.

The patient, now back on the commode with the vesical and rectal pressure catheters still in situ, is instructed to void, and the detrusor pressure and urine flow rate are recorded simultaneously. Detrusor pressure at maximum flow ($p_{det}Q_{max}$) and flow rate are recorded. The urodynamicist and any other staff in the room usually leave the room during the voiding phase to allow for privacy, unless video urodynamics are performed.

Voluntary initiation of a detrusor contraction is usually required for normal micturition and this is normally sustained until the bladder is empty, although some women can void by just relaxing their pelvic floor. The pressure rise is dependent on the outlet resistance and on the contraction of the detrusor itself (Table 32.1): if the detrusor pressure is low with low flow rates, the detrusor is defined as underactive; if the pressure is high with low or normal flow rates, this may be indicative of bladder outlet obstruction. If the detrusor muscle is functioning normally, then abdominal straining should not be required for bladder emptying. Many nomograms have been suggested as being able to diagnose bladder outlet obstruction and detrusor underactivity in women; however, neither the ICS nor the International Consultation on Incontinence has yet adopted a nomogram for women and none has been widely used or universally accepted. In general, however, a sustained detrusor pressure of more than 20 cmH_2O and a flow rate of less than 12 mL/s with or without a residual urine are indicative of bladder outlet obstruction in women [20].

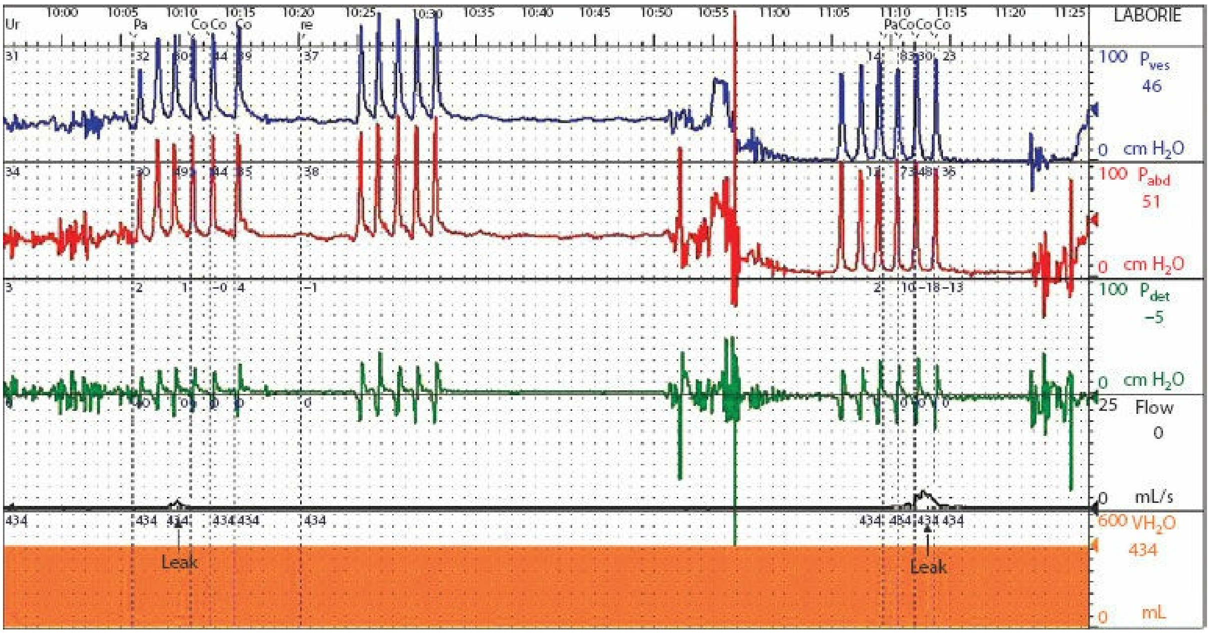

Figure 32.9 Cystometrogram showing urodynamic stress incontinence (leak) with coughing. (p_{det}, detrusor pressure; p_{abd}, intra-abdominal pressure; p_{ves}, vesical pressure; flow rate in mL/s; V_{H2O}, volume of filling medium infused.

Table 32.1 Lower Urinary Tract Function according to Clinical Diagnosis and Detrusor and Urethral Function during the Filling and Voiding Cycles of Micturition with Possible Urodynamic Diagnosis

	Filling phase		
	Urodynamics		
Clinical diagnosis	Detrusor function	Urethral function	Urodynamic diagnosis
Normal	Normal	Competent	Normal
SUI	Normal	Incompetent	USI
OAB "dry"	Overactive	Competent	DO
OAB "wet"	Overactive	Competent	DOI
OAB "dry" + SUI	Overactive	Incompetent	DO + USI
OAB "wet" + SUI	Overactive	Incompetent	DOI + USI
(Mixed urinary incontinence)			

	Voiding phase		
	Urodynamics		
Clinical diagnosis	Detrusor function	Urethral function	Urodynamic diagnosis
Normal	Normal	Relaxed	Normal
POP	Normal	Obstructed	High pressure/low flow (BOO)
Difficulty voiding	Underactive	Relaxed	Low flow/low pressure

Abbreviations:SUI, stress urinary incontinence; OAB, overactive bladder; USI, urodynamic stress incontinence; DO, detrusor overactivity; DOI, detrusor overactivity incontinence; POP, pelvic organ prolapse; BOO, bladder outlet obstruction.

A further rise in detrusor pressure after the completion of voiding, known as an "after contraction," is sometimes seen at the end of a completed void, in patients with DO; however, the significance of this finding is unknown. The patient is asked to cough at the end of voiding to check for quality control and to ensure that the p_{ves} measuring catheter has not moved out of the bladder during voiding. If it has, then the p_{ves} data for voiding should be regarded as unreliable and consideration given to repeating the voiding phase if the required information cannot be extracted.

PITFALLS OF CYSTOMETRY

To ensure accurate measurements, in a fluid-filled system, the bladder line, rectal line, and all tubing should be flushed to ensure that all air bubbles have been removed before recording begins. In addition, all connections should be tight, as any leak will cause errors in the pressure measurements recorded. Pressure values will tend to be lower, and recorded with a delay, if there are bubbles or leaks in the pressure system.

Rectal contractions can sometimes be seen on the recording trace (Figure 32.10) and may be misinterpreted as DO; it is, therefore, important to be aware of rectal activity. If possible, the patient should have an empty rectum for the test. If the rectal line slips slowly during the recording, the p_{abd} line will be seen to drift downward, which could be incorrectly interpreted as a rise in the detrusor pressure and reduced compliance: careful examination of the vesical line shows the bladder pressure to be constant and should allow this artifact to be noticed and corrected.

Quality control at the start of each cystometrogram is vital and should be repeated at regular intervals during the test and again at the end of the test to ensure that good pressure transmission is continuing. This is done by asking the patient to cough and seeing an equal rise in the cough spikes in both the abdominal and vesical lines with no rise (other than a small biphasic deflection in a fluid-filled system) on the detrusor line.

NORMAL CYSTOMETRY

Cystometry of a normal bladder shows the following:

- Residual urine of less than 50 mL
- First desire to void between 150 and 250 mL
- Capacity (taken as SDV) between 300 and 600 mL
- Little or no detrusor pressure rise on filling (Figure 32.11)

- Absence of detrusor contractions during the filling phase
- No leakage on coughing
- No detrusor contraction provoked by coughing or running water (precipitating factors)
- Maximum voiding detrusor pressure of less than 50 cmH_2O, with a maximum flow rate greater than 15 mL/s for a volume greater than 150 mL

If cystometry has been performed for storage symptoms, then at the end of the test, the question that has to be answered is: "Did the cystometry succeed, partially succeed, or fail to reproduce the patient's symptoms?"

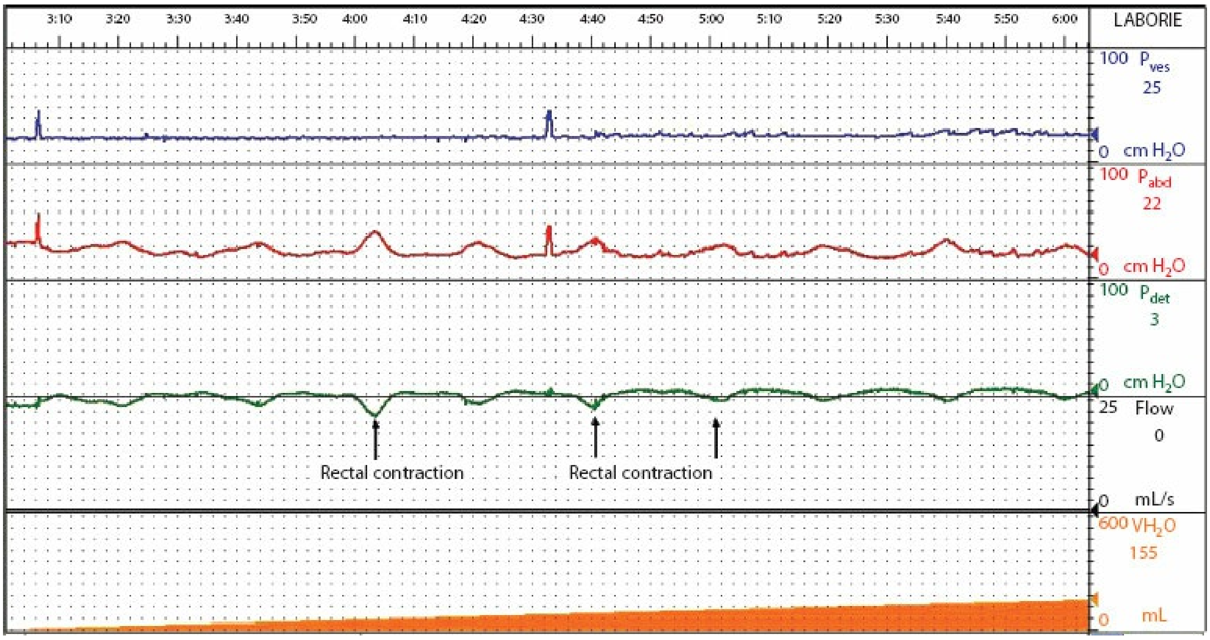

Figure 32.10 Cystometrogram showing rectal contractions. (p_{det}, detrusor pressure; p_{abd}, intra-abdominal pressure; p_{ves}, vesical pressure.)

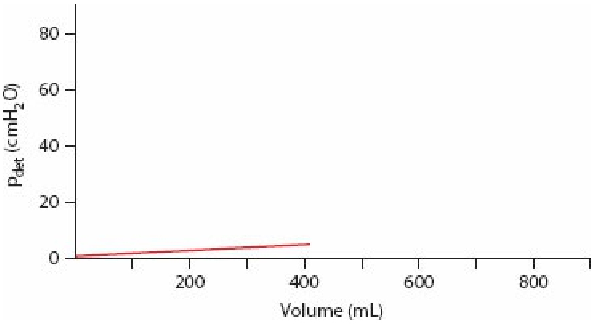

Figure 32.11 Normal filling cystometrogram annotation showing minimal increase in detrusor pressure (p_{det}). The filling speed is 50 mL/min, the patient is seated, the bladder capacity is 400 mL, and the first desire to void is at 160 mL.

CONCLUSION

Cystometry is a component of invasive urodynamic studies used to investigate lower urinary tract dysfunction. It is vital that women are assessed with a proper history and examination, and the results of the cystometric findings are evaluated in light of the signs and symptoms with the aid of voiding diaries. The majority of women will have their symptoms explained during urodynamics, and/or further management decisions can be made from conventional cystometry. Further cystometry can be performed using ambulatory monitoring over a longer period of time and in more natural circumstances or together with video cystourethrography when a simultaneous assessment of the anatomy is desirable.

33 Tests of Urethral Function

Kristi L. Hebert, Barry G. Hallner, Ryan M. Krlin, and J. Christian Winters

URETHRAL ANATOMY AND MECHANISMS OF URETHRAL CONTINENCE

Adequate bladder outlet resistance is essential in order to maintain urinary continence in women, particularly during periods of increased intra-abdominal pressure. The anatomy and function of the urethra is an important determinant of continence. The female urethra throughout its length has a complex luminal architecture, which serves a dual function as a conduit as well as a barrier protecting the underlying stroma from urinary irritants. The distance between the bladder neck and external urethral meatus determines the anatomic length of the urethra. The urethral mucosa contains many infoldings and is supported by loose elastic connective tissue, containing bundles of collagen fibers. This promotes distention during voiding as well as coaptation (or urethral seal effect) during storage. The mucosa, submucosal tissues, and the periurethral fascia connective tissues promote urethral closure and the urethral seal effect. The urethra contains a complex of smooth and striated muscles, which contribute to the sphincteric mechanism. A relatively thick layer of inner longitudinal smooth muscle continues from the bladder to the external meatus to insert into periurethral fatty and fibrous tissue. A rather thin layer of circular smooth muscle envelops the longitudinal fibers throughout the length of the urethra. It is thought that the longitudinal smooth muscle of the urethra contracts in coordination with the detrusor during micturition to shorten and widen the urethra [1]. The urethral smooth muscle composed of circular and longitudinal fibers joins the detrusor muscle in the base of the bladder to form the intrinsic sphincter mechanism, with its predominant function in the proximal urethra and bladder neck [2]. The striated urethral sphincter invests the distal two thirds of the female urethra [3]. It is composed exclusively of delicate type I (slow-twitch) fibers surrounded by abundant collagen. Proximally, near the midurethra, it forms a complete ring around the urethra that corresponds to the zone of highest urethral closure pressure. This striated muscular complex adds resting tone to the urethra, further enhancing urethral closure. DeLancey et al. [2,4,5], as well as Petros and Ulmsten [6], have contributed greatly to the current understanding of the anatomy of urethral support and function of the urethral continence mechanism. The pubocervical and periurethral fascia support the bladder base and proximal urethra respectively in a sling-like fashion, which is attached bilaterally to the arcus tendineus fascia pelvis (ATFP). In addition, the pubourethral ligament complex provides stability to the midurethra. During periods of increased intra-abdominal pressure, the urethra is closed by the hammock of support created by the periurethral fascia, which increases urethral resistance, thereby promoting continence. This has been proposed as the “hammock hypothesis” [2,4]. In addition, this hammock of support stabilizes the urethra and prevents excessive urethral descent. This facilitates closure of the urethra against the pubourethral ligaments during contraction of the pubococcygeus muscles (levator ani) during periods of increased intra-abdominal pressure. The combination of anatomic support and midurethral closure during periods of increased intra-abdominal pressure is known as the “integral theory” [6] (Figure 33.1). Discrete defects in the pubocervical or periurethral fascia, or detachment of these structures from the ATFP, results in loss of bladder neck and proximal urethral support, creating “urethral hypermobility.” This loss of urethral support prevents the hammock effect of urethral closure or compression of the urethra against the pubourethral ligaments [6]. Thus, defects in the anatomic support of the female urethra can disrupt urethral and pelvic floor function, which should maintain continence during periods of increased intra-abdominal pressure.

Assessment of Urethral Anatomy

Physical examination: An examination of the external genitalia and anterior vaginal wall will provide substantial information regarding urethral anatomy. Urethral caruncles, urethral prolapse, Skene’s gland obstruction, and inflammation are easily detected. The presence of urethral scarring or induration may also suggest postoperative or alternative conditions, which could adversely affect urethral function. Vaginal wall thinning or a pale appearance to the urethra implies vaginal atrophy, which can predispose to certain urological conditions. Lastly, a bulging or purulent expressate is suspicious for urethral diverticulum, which could predispose to leakage, infection, and rarely obstruction. A loss of urethral support can be assessed using a half-speculum to examine the anterior vaginal wall in the resting and straining state. Urethral hypermobility is usually easily discernable on examination by the classic rotational appearance of the urethra when the patient is asked to strain down. In most instances, a visual assessment is enough to confirm the presence of urethral hypermobility. In select instances, a cotton swab test may be used, which is performed by inserting a sterile lubricated cotton swab into the urethra and advancing it into the bladder. It is gently withdrawn until resistance is felt, insuring proper positioning at the urethrovesical junction. The angle of deflection with straining should be measured with a goniometer. Urethral hypermobility is defined as the maximal straining angle of more than 30° from the horizontal [7] or from the resting angle. This test has demonstrated good interobserver reliability [8,9]. In most cases, this test is unnecessary and may be uncomfortable, so its use should be limited to those cases where it will change the course of treatment.

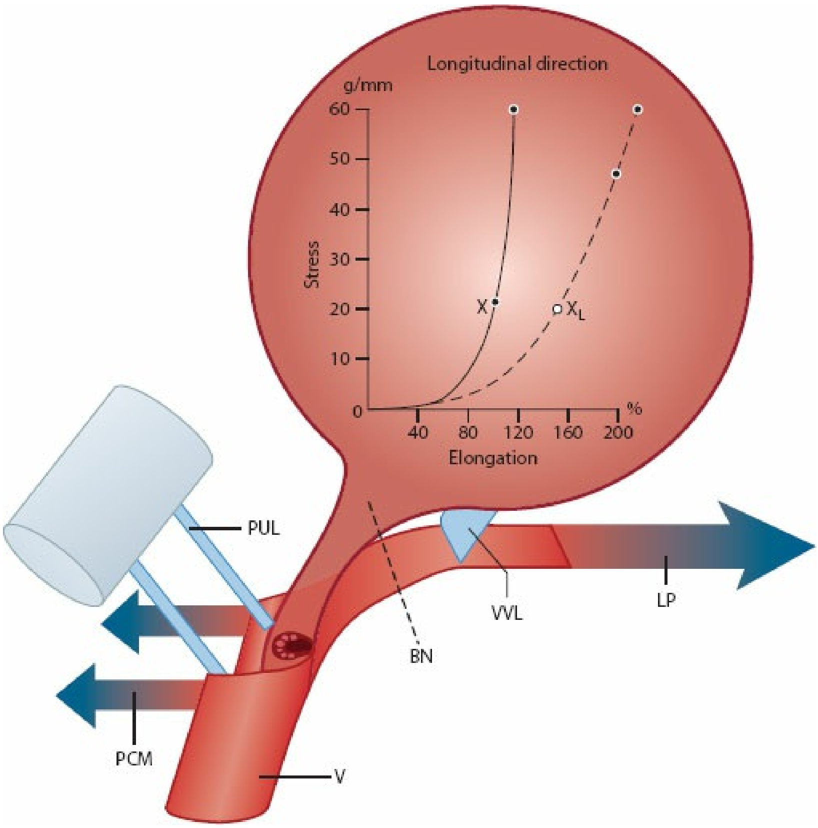

Figure 33.1 Urethral anatomy: Influence of vaginal laxity on muscle force transmission and urinary continence. Inset, Stress extension curve of vagina. BN, bladder neck; LP, levator plate; PCM, pubococcygeus muscle; PUL, pubourethral ligament; V, vaginal hammock; VVL, vaginal attachment to the bladder base; X, normal elasticity; XL, vaginal laxity. The authors propose that an increase in urethral pressure before cough transmission proves that an active continence mechanism is involved in preventing stress urinary incontinence. (Reproduced from Petros PE and Ulmsten UI, *Scand J Urol Nephrol Suppl*, 153, 1, 1993. With permission.)

Ultrasound

Different ultrasound techniques have been used to quantify bladder neck mobility, including transrectal, transvaginal [10], perineal [11], and introital. The transperineal approach is the most commonly used. The bladder neck is identified, and by performing systematic measurements of descent with relation to the symphysis pubis, normal values of descent have been reported with good interobserver reliability [12]. This modality of ultrasound assessment is expensive and requires specific training in order to develop proficiency. In addition, the precise role of ultrasound imaging has not been determined.

FLUOROSCOPY (VIDEOURODYNAMICS)

Urodynamics is a test of vesicourethral function in which specific provocation tests are undertaken to evaluate urethral competence. Videourodynamics (VUDS) is the synchronous measurement and display of urodynamic parameters with radiographic visualization of the lower urinary tract. During VUDS, the clinician can better appreciate the interrelationships between the various urodynamic parameters, with the periodic sampling of fluoroscopic images during filling, voiding, and provocative maneuvers such as leak point pressure (LPP) measurement. The addition of concomitant cystourethrography to urodynamics does allow the clinician to better evaluate the state of the bladder neck and the site of urethral obstruction. VUDS is a useful test in the diagnosis of detrusor sphincter dyssnergia, acquired voiding dysfunction (AVD), and anatomic urethral obstruction. According to the 2012 AUA Guidelines on Adult Urodynamics, VUDS studies are useful in providing additional anatomic detail, particularly in patients with neurogenic bladder, as well as assisting in identifying the site(s) of bladder outlet obstruction [13].

Detrusor External Sphincter Dyssynergia

Detrusor external sphincter dyssynergia (DESD) is defined by the International Continence Society as a detrusor contraction concurrent with an involuntary contraction of the urethral and/or periurethral striated muscle [19]. Detrusor contractions occur with synchronous contractions of the urethral and periurethral striated muscles. It represents inappropriate sphincter activity during voiding, creating functional obstruction of the urethra. This condition is a consequence of underlying neurological disease and can be seen in suprasacral spinal cord injury (SCI), multiple sclerosis (MS), and transverse myelitis [13]. True DESD may only exist in the presence of a neurological lesion that lies within the brain stem or suprasacral spinal cord. In DESD, the contraction of the external sphincter (and increase in EMG activity) occurs prior to the onset of the detrusor contraction. The classic appearance of DESD with VUDS shows a dilated proximal urethra and a narrowed distal urethra associated with increased EMG activity and an involuntary detrusor contraction (Figure 33.2).

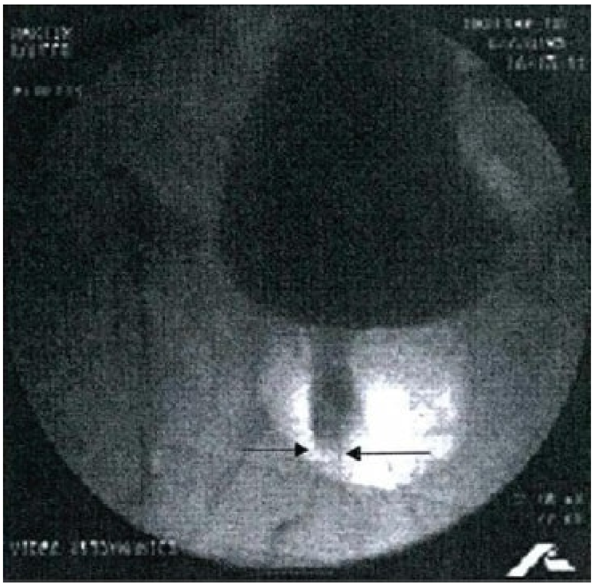

Figure 33.2 X-ray obtained at P_{det} at Qmax in a patient with DESD shows the classic picture of complete obstruction at the membranous urethra (arrows) and a “Christmas tree”–shaped bladder. *Abbreviation:* DESD, detrusor external sphincter dyssynergia. (Reproduced from Jerry B et al., eds., *Atlas of Urodynamics*, 2nd ed., Blackwell Publishing, Oxford, U.K., 2007. With permission.)

Acquired Voiding Dysfunction: Hinman’s Syndrome

With AVD in the absence of a neurological abnormality, the patient involuntarily (and subconsciously) contracts the external urethral sphincter during voiding [14]. The fluoroscopic images of these contractions are identical to those seen in DESD since both cause functional urethral obstruction (Figure 33.3). In contrast, in AVD the detrusor contraction occurs prior to the subconscious contraction of the external sphincter. Concentric needle electrode provides a superior signal source compared with the surface electrode in the evaluation of AVD.

Anatomic Urethral Obstruction

The ICS defines anatomic obstruction in women as reduced urine flow rate and/or the presence of a raised postvoid residual urine and an increased detrusor pressure [19]. Nitti et al. proposed that urethral obstruction be defined as radiographic evidence of obstruction between the bladder neck and the distal urethra in the presence of a sustained detrusor contraction [16]. Urethral obstruction in women causes voiding and postvoiding symptoms (weak stream, hesitancy, and postvoid dribbling). As a consequence of incomplete bladder emptying, storage symptoms may also occur. The two most common causes of anatomic urethral obstruction in women are pelvic organ prolapse (POP) and complications after anti-incontinence surgery. According to the 2012 AUA Guidelines on Adult Urodynamics, clinicians may perform pressure-flow studies in patients with refractory urgency after bladder outlet procedures to evaluate for bladder outlet obstruction [13]. With the use of VUDS, the site of obstruction is defined as the narrowest point in the urethra during voiding cystourethrography.

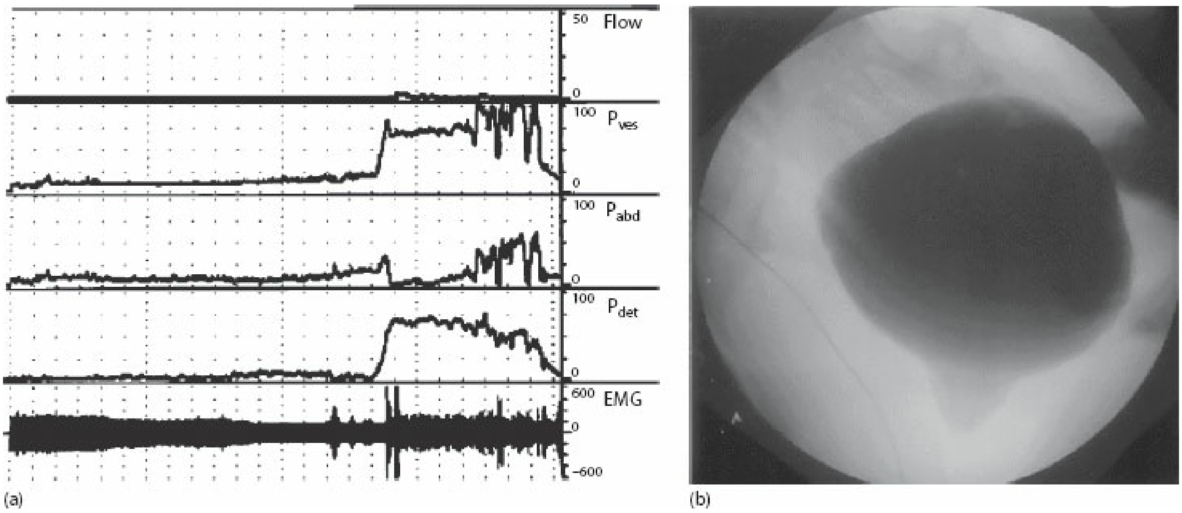

Figure 33.3 VUDS in a 33-year-old woman with AVD. (a) High pressure, low flow is associated with increased EMG activity. (b) Fluoroscopic visualization of urethra during voiding shows dilated proximal urethra with point of obstruction at the external sphincter. *Abbreviations:* AVD, acquired voiding dysfunction; EMG, electromyography; P_{ves}, intravesical pressure; P_{abd}, abdominal pressure; P_{det}, detrusor pressure; VUDS, videourodynamics. (Reproduced from Carlson KV et al., *J Urol*, 165(1), 143, January 2001. With permission.)

In patients with high-grade POP, descent of the anterior vaginal wall may create urethral kinking and compression [17]. Documenting the presence of stress urinary incontinence (SUI) in patients with the prolapse reduced is helpful in the preoperative assessment of women with high-grade POP. SUI occurring after prolapse correction is known as occult SUI. To diagnose occult SUI, the prolapse may be reduced with vaginal packing, rectal swabs, a speculum blade, or pessary. VUDS is helpful in demonstrating both urethral obstruction and occult SUI [18] (Figures 33.4 and 33.5). Prolapse should be reduced during urodynamic testing to assess for occult SUI, particularly in the setting of detrusor dysfunction or lower urinary tract symptoms.

In women with high-stage anterior compartment prolapse, the 2012 AUA Guidelines on Adult Urodynamics recommends that all patients undergoing surgical repair should undergo stress testing with reduction of the prolapse. In women with high-stage anterior compartment prolapse and associated lower urinary tract symptoms, urodynamics with LPP measurement should be performed with the prolapse reduced [13].

While urethral function can be inferred from physical examination, anatomic and radiographic tests, and cystometry (Figure 33.6), more accurate assessments of urethral function are commonly needed. Urethral function may be more accurately characterized in a number of ways: LPP measurement, urethral pressure profilometry (UPP), and electromyography (EMG). A description of these techniques is included.

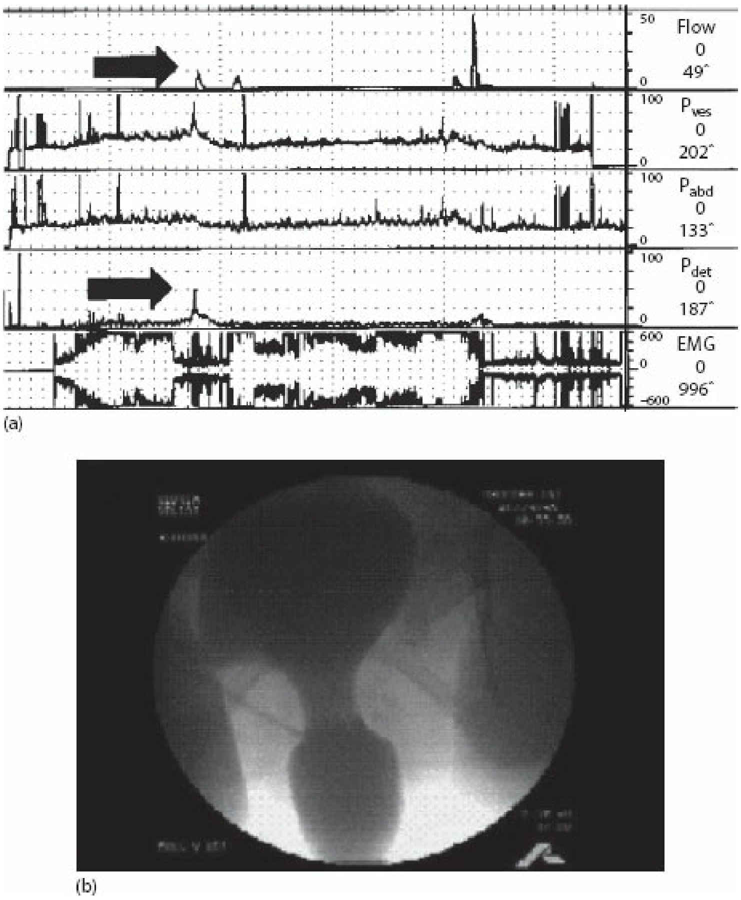

Figure 33.4 VUDS in a 65-year-old woman with grade 4 anterior compartment prolapse. (a) At the arrows, she voids with detrusor pressure (P_{det}) of 50 cmH_2O and a flow of 6 mL/s, indicating urethral obstruction. (b) Voiding cystogram taken at the arrow shows a large cystocele obscuring the urethra and causing urethral obstruction. *Abbreviations:* EMG, electromyography; P_{ves}, intravesical pressure; P_{abd}, abdominal pressure; VUDS, videourodynamics. Figure 33.5 The same 65-year-old woman as in Figure 33.4 with her POP reduced. (a) At the arrows, she voids with a detrusor pressure (P_{det}) of <10 cmH_2O and a flow of 49 mL/s. VLPP was about 90 cmH_2O. (b) Voiding cystogram taken at the arrow shows high flow and low pressure. *Abbreviations:* EMG, electromyography; P_{ves}, intravesical pressure; P_{abd}, abdominal pressure; POP, pelvic organ prolapse; VLPP, valsalva leak point pressure; VUDS, videourodynamics.) (Reproduced from Flisser AJ and Blaivas JG, *Urol Clin North Am*, 29(3), 515, August 2002. With permission.)

ABDOMINAL LEAK POINT PRESSURE

Another way to assess urethral function is with the measurement of LPPs. There are two methods of LPP assessment that analyze different functional areas of the lower urinary tract. The detrusor leak point pressure (DLPP), as defined by the ICS, is the lowest detrusor pressure at which urine leakage occurs in the absence of either a detrusor contraction or increased abdominal pressure [19]. It is not a test of urethral function but rather a test examining the relationship of bladder storage function and urethral resistance in patients with neurogenic bladder. In contrast, the abdominal leak point pressure (ALPP) is a measure of urethral function. The ALPP, as defined by the ICS, is the lowest intravesical pressure (P_{ves}) at which urine leakage occurs because of increased abdominal pressure in the absence of a detrusor contraction [19].

McGuire et al. introduced the concept of ALPP in 1993 as a means of differentiating urinary incontinence due to either urethral hypermobility or ISD [20]. This measurement is used to quantify the *stress competence* of the urethra or the ability of the urethra to maintain continence during periods of increased intra-abdominal pressure. McGuire proposed that ALPP is a measure of sphincter strength. In a normally positioned and closed urethral sphincter, increased abdominal pressure does not open the sphincter—thus, there is no normal ALPP. Urine leakage can be caused only by an increase in abdominal pressure when the urethra is abnormal. Low values for ALPP implies less urethral resistance to *protect* against leakage during increased intra-abdominal pressure; thus lower ALPP values suggest *weaker* sphincters. Thus, ALPP cannot be quantified if the subject does not demonstrate SUI during urodynamic testing. In addition, the detrusor pressure at the time of ALPP testing must be low. High detrusor pressure (due to detrusor overactivity, or poor bladder compliance) at the time of ALPP testing may result in the false impression that urethral function is impaired [21].

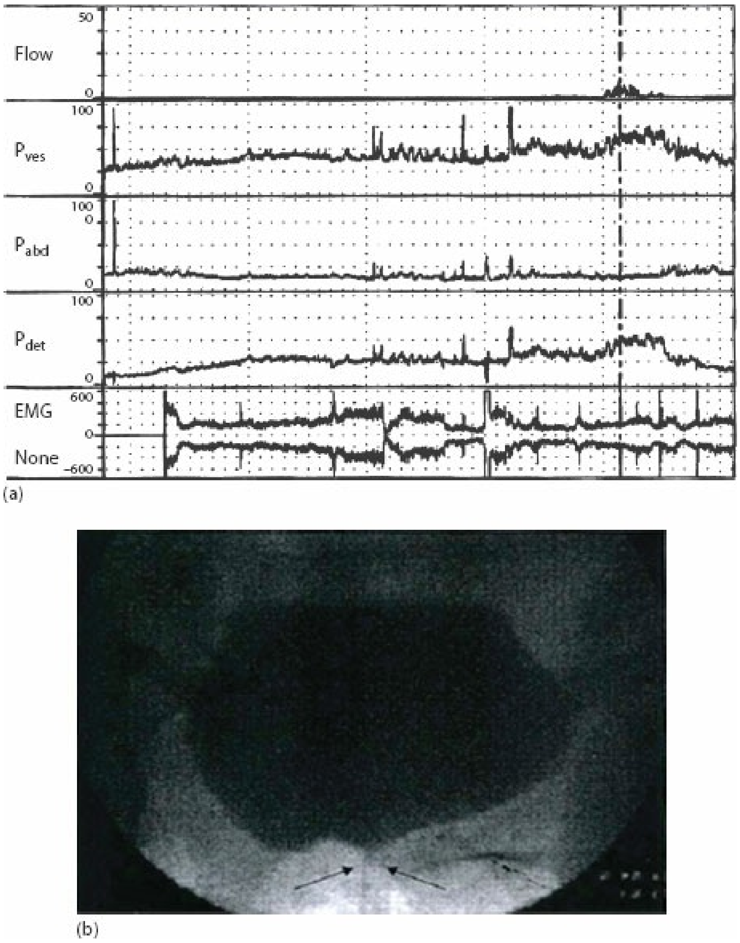

Figure 33.6 Urethral obstruction 5 years status post autologous fascial pubovaginal sling. (a) Urodynamic tracing. P_{det} at Q_{max} = 50 cmH_2O and Q_{max} = 6 mL/s (vertical dashed line). (b) X-ray exposed at Q_{max} shows a narrow urethra just distal to the vesical neck (arrows). *Abbreviations:* EMG, electromyography; P_{ves}, intravesical pressure; P_{abd}, abdominal pressure; P_{det}, detrusor pressure. (Reproduced from Reproduced from Jerry B et al., eds., *Atlas of Urodynamics*, 2nd ed., Blackwell Publishing, Oxford, U.K., 2007. With permission.)

Technique of ALPP

An acceptable technique to measure ALPP involves placing a dual-lumen urodynamic catheter into the bladder. Cystometry then proceeds until the bladder has been filled to 150 cc. The patient is then asked to perform a Valsalva maneuver by gradually increasing his or her intra-abdominal pressure until he or she leaks (Valsalva leak point pressure [VLPP]) (Figure 33.7). The lowest P_{ves} at which leakage occurs is defined as the ALPP. If there is no urine leakage with a bladder volume of 150 mL, the test is repeated at 50 mL increments until maximum cystometric capacity is reached. Measurements at capacity may only be recorded if there is no spontaneous detrusor activity.

If the patient is not able to generate a Valsalva pressure sufficient enough to produce leakage, the patient is asked to cough several times with increasing strength until leakage occurs. Compared to the straining performed with a Valsalva maneuver, coughing generates a faster increase in intra-abdominal pressures. As such, precise measurements are more difficult to obtain with coughing. Once leakage has been observed, the force of the cough is reduced until it generates the minimal amount of abdominal pressure required to produce leakage to determine the P_{ves} at which leakage occurs induced by cough

(cough leak point pressure [CLPP]). Although the term ALPP is often used interchangeably with VLPP, it should not be. The ALPP represents measuring the vesical pressure at which leakage is associated with increasing abdominal pressure. As noted earlier, this may happen by Valsalva (VLPP) or by cough (CLPP). The CLPP is usually measured in the absence of a VLPP, because it is harder to quantify and is usually higher. Thus, VLPP and CLPP are two types of the ALPP. Thus, ALPP is the preferred term for this technique of urethral pressure measurement.

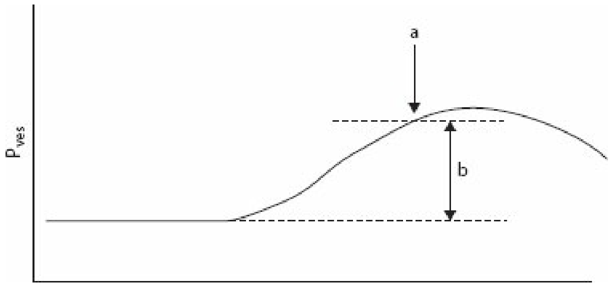

Figure 33.7 Measurement of VLPP: Patient is asked to bear down progressively while holding breath. Leakage is recorded (arrow) at the precise moment that fluid is observed at urethral meatus. The rise on intravesical pressure over baseline (b) represents VLPP. *Abbreviations:* P_{ves}, intravesical pressure; VLPP, valsalva leak point pressure. (Reproduced from Bump RC et al., *Am J Obstet Gynecol*, 173(2), 551, August 1995. With permission.)

Patient position is important. For example, if patients only leak when standing, then the test may need to be done in the standing position. Additionally, in patients who are suspected of having SUI but do not leak during UDS testing with the catheter in place, the AUA Adult Urodynamics Guidelines recommend that stress testing be repeated with the catheter removed. The panel cited studies of patients who leak without the catheter in place despite negative UDS testing—suggesting that the urethral catheter may *mask* the presence of SUI in certain patients [13].

Bladder Volume and ALPP

ALPP testing has been correlated with bladder volume in the majority of clinical studies. Theofrastous et al. performed a study of 120 women with SUI who underwent VLPP testing at bladder volumes of 100, 200, and 300 mL and at maximum cystometric capacity [22]. The authors found that women who leaked with Valsalva maneuvers at lower bladder volumes had worse measures of incontinence compared with women who leaked at higher volumes. Also, they found that the mean VLPP was higher at lower bladder volumes compared to VLPP at maximum cystometric capacity. The authors concluded that VLPP in women with SUI decreases significantly with bladder filling.

Faerber and Vashi also found that VLPP decreased significantly with increasing bladder volumes [23]. Using VUDS, they found that a bladder volume of 250–300 cc allowed for the most appropriate classification of patients. Miklos et al. sought to assess whether ALPP is affected by the method of provocation, the presence of an intravesical catheter, and bladder volume [24]. With respect to bladder volume, they too noted a decrease in ALPP with increasing bladder volume (Figure 33.8). With Valsalva testing, the ALPP decreased by 19 cmH_2O as the bladder volume rose from 150 cc to >400 cc. With coughing, the ALPP decreased by 35 cmH_2O as the bladder volume rose from 150 cc to >400 cc. In contrast, Petrou et al. found no significant difference in VLPP at various bladder volumes [25]. They concluded that the volume in the bladder does not alter the category of SUI or statistically change the VLPP determination.

Urodynamic Catheter Size and Location

Bump et al. also studied the effect of urodynamic catheter size on VLPP [26]. Using an 8 Fr urodynamic catheter, they found that the VLPP was 9.2 cmH_2O higher than when using a 3 Fr urodynamic catheter—$p = 0.01$. Miklos et al. also noted a significant decrease in both CLPP and VLPP at all bladder capacities when removing the transurethral catheter and using only an intravaginal catheter [24]. There is no debate that a transurethral catheter has some effect on the ALPP measurement; however, the precise magnitude of this effect is unclear.

Test–Retest Reliability

Bump et al. found the average pressure differences between the first and second VLPP to be clinically and statistically insignificant, regardless of urodynamic catheter size [26]. The pressure difference between the two consecutive VLPPs was 2.2 cmH_2O using the 8 Fr urodynamic catheter and 1.5 cmH_2O using the 3 Fr urodynamic catheter. Nager et al. published reference urodynamic values for the 655 stress incontinence women that comprised the Stress Incontinence Surgical Treatment Efficacy Trial (SISTEr) [27]. All filling cystometrograms were performed with subjects in the standing position. All vesical pressures were measured with a urodynamic catheter 8 Fr or smaller in size. Each of the 428 patients with measurable VLPPs had reproducible values. For 50% of the women, the VLPP intrapatient range was ≤ 15 cmH_2O. On average, there was only a 10 cmH_2O difference between the mean VLPP (117 cmH_2O) and the minimum VLPP (107 cmH_2O).

Factors Associated with ALPP

Fleischmann et al. studied the relationships between VLPP, urethral hypermobility, and incontinence severity in 65 women with SUI [28]. A linear regression model showed no correlation of VLPP with urethral hypermobility in women with SUI. In addition, no significant difference in incontinence episodes or pad weight was seen in women with urethral hypermobility and a VLPP < 60 cmH_2O compared to women with no urethral hypermobility and a VLPP < 60 cmH_2O. Lemack et al. sought to determine which clinical and demographic factors were associated with women undergoing either Burch colposuspension or autologous rectus fascial sling as part of the SISTEr trial [29]. A multivariate analysis showed that older age, lower body mass index (BMI), smaller bladder capacity, higher maximum flow rate, and lower voiding pressures were all independently associated with lower VLPP. Each 1-year increase in age resulted in a decrease in VLPP of 0.77 cmH_2O. Each one-unit increase in BMI value resulted in an increase in VLPP of 0.66 cmH_2O. Urethral hypermobility, as assessed by cotton swab testing, did not achieve a significant association with VLPP when controlling for POP-Q stage. The authors concluded that cotton swab testing had no role in predicting VLPP in women with urethral hypermobility and SUI. Thus, it appears that there is little reliable correlation of urethral hypermobility with ALPP. However, factors such as advancing age and weight do appear to have some correlation with ALPP measurement.

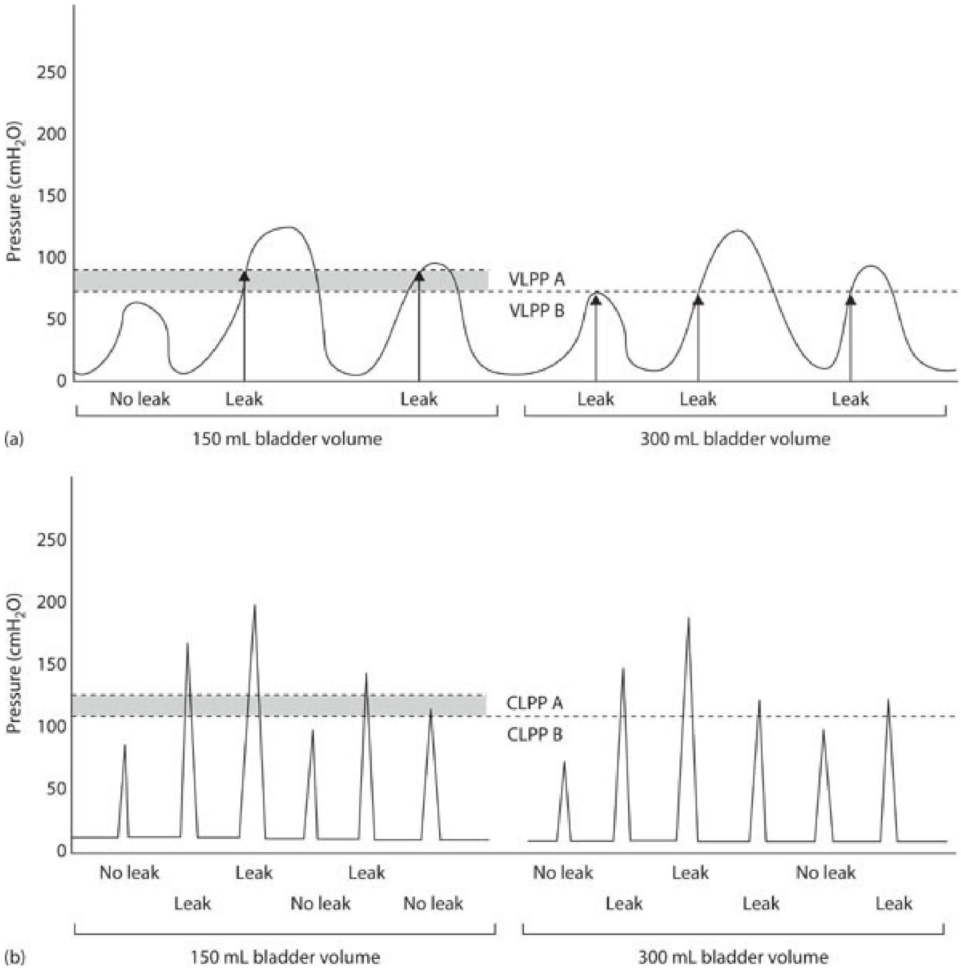

Figure 33.8 Effect of bladder volume on (a) VLPP and (b) CLPP. (Reproduced from Benson J, Electrophysiologic testing, in Walters M and Karram M, eds., *Urogynecology and Reconstructive Pelvic Surgery*, 2nd ed., Mosby, St. Louis, MO, 1999, p. 100. With permission.)

Effect of Pelvic Organ Prolapse on ALPP

POP often artificially elevates VLPP because the prolapse provides a mechanism that dissipates the effect of the increased abdominal pressure on the urethra [21]. As such, it is recommended that VLPP testing be performed with and without prolapse reduction to identify if patients are at risk for occult SUI. Romanzi et al. studied the effect of genital prolapse on voiding in 60 women [30]. All of the women with grade 3 or 4 cystocele who had SUI (either symptomatic or occult) also had ALPP < 60 cmH_2O, which they defined as ISD. Gallentine et al. prospectively evaluated 24 patients with high-grade POP to determine the change in ALPP with reduction of the POP [17]. The prolapse reduction was performed using gauze packing and a speculum blade. The mean decrease in ALPP was 59 cmH_2O after prolapse reduction. The decrease in ALPP with prolapse reduction was much greater in patients with vaginal vault prolapse than in patients with cystocele alone. Gilleran et al. evaluated the effect of cystocele reduction by a vaginal gauze pack on urodynamic studies [31]. Occult SUI was seen in 6% of women, and the mean VLPP of 54 cmH_2O in these women suggested ISD. UDS may be helpful in determining the presence of urethral obstruction or occult SUI associated with POP.

In women with high-stage anterior compartment prolapse, the 2012 AUA Guidelines on Adult Urodynamics recommends that all patients undergoing surgical repair of high-grade anterior compartment prolapse undergo stress testing with the prolapse reduced. In women with high-grade prolapse and associated urinary symptoms, urodynamics with LPP measurement with the prolapse reduced should be performed [13].

Relationship of ALPP to Incontinence Severity

Early studies reported significant correlation between VLPP and measures of incontinence severity. Nitti et al. evaluated 64 women with SUI using the Stress, Emptying, Anatomy, Protection, and Instability (SEAPI) grade [32]. Using VUDS, the authors found that a VLPP of 90 cmH_2O or less did correlate highly with more severe symptoms of SUI. Also, Nager et al. demonstrated significant decreases in VLPP with increasing severity of incontinence as determined by Stamey grade ($p < 0.01$) [33]. However, they found no correlation between VLPP and pad weight or the 16-question QOL questionnaire from the "Q" section of the SEAPI. Albo et al. sought to examine the relationship between severity measures of urinary incontinence in women undergoing either Burch colposuspension or autologous rectus fascial sling as part of the SISTEr trial [34]. Weak-to-moderate correlations were observed between Medical, Epidemiological and Social Aspects of Aging (MESA), incontinence episode frequency, pad weight, Incontinence Impact Questionnaire (IIQ), and Urogenital Distress Inventory (UDI). However, VLPP correlated poorly with all incontinence severity measures. The authors concluded that VLPP is not associated with symptom severity, quantity of urine loss, or QOL impairment. They stated that VLPP neither reflects the bother from incontinence nor takes into account lifestyle activity.

Relationship of ALPP and Stress Continence Outcomes

Rodriguez et al. evaluated the role of prospective VLPP in predicting the outcome of distal urethral polypropylene sling (DUPS) surgery [35]. They divided 174 patients into 4 groups based on VLPP: no leakage, VLPP > 80 cmH_2O, VLPP 30–80 cmH_2O, and VLPP < 30 cmH_2O. The groups were matched with respect to age, number of previous surgeries, and severity of SUI symptoms. When evaluating outcomes based on both daily pad use and patient-driven questionnaires, all groups reported similar success 14 months after DUPS, regardless of preoperative VLPP. The authors concluded that VLPP is more likely a measure of incontinence severity than a test defining the mechanism of incontinence. Nager et al. sought to determine the prognostic value of preoperative urodynamic results in women with SUI as part of the SISTEr trial [36]. Women were eligible for the study if they had predominant SUI symptoms, a positive cough stress test, a bladder capacity > 200 mL, and urethral hypermobility. The association of VLPP and success, controlling for the treatment group, was compared using ANOVA. Women who failed either Burch colposuspension or autologous rectus fascial sling did not have a lower mean VLPP compared to those that achieved success at the 24-month stress-specific outcome assessment (Table 33.1). Note that overall treatment success required a negative pad test, no urinary incontinence on a 3-day diary, a negative stress test, no self-reported SUI symptoms, and no retreatment for SUI. The authors concluded that the level of VLPP did not predict the success of outcomes after either Burch colposuspension or autologous rectus fascial sling procedures in women with pure or predominant SUI. The Value of Urodynamic Education (ValUE) trial reported no improvement in 12-month outcomes between women with stress-predominant urinary incontinence randomized preoperatively to an office evaluation alone and preoperative urodynamic testing, which included LPP testing on all patients. In this study, urethral pressure profiles were performed only if it was a routine of each center. The authors concluded in well-selected women with uncomplicated SUI that UDS did not enhance predicting surgical outcomes [37]. It should be mentioned, however, that after urodynamic testing, women in the urodynamic-testing group were significantly less likely to receive a diagnosis of an overactive bladder with incontinence, an overactive bladder without incontinence, or suspected intrinsic sphincter deficiency, and they were significantly more likely to receive a diagnosis of voiding-phase dysfunction than were those in the evaluation-only group—suggesting that UDS did change the clinician's diagnosis before surgery. In this study, these changes in urodynamic diagnosis did not result in overall changes in surgical treatment [37]. It should be considered that this study group was a highly select group of pelvic surgeons using a rigorous preoperative assessment—and is likely not representative of the overall pelvic surgeon milieu treating women with SUI. In this group, these changes of UDS diagnosis may have induced changes in treatment decisions. Additionally, Zimmern et al., in a follow-up evaluation of the ValUE database, concluded that in the clinical diagnosis of women with SUI, physician confidence increased after doing UDS testing [38].

Table 33.1 VLPP Does Not Predict Success of Either Burch or Pubovaginal Sling

	Burch	**Pubovaginal sling**

Mean cmH_2O (SD)/No.	Overall outcome	
Success	115(40)/57	117(33)/71
Failure	115(37)/104	121(39)/105
Mean cmH_2O (SD)/No.	Stress-specific outcome	
Success	116(40)/80	117(34)/109
Failure	114(37)/87	125(41)/72

URETHRAL PRESSURE PROFILOMETRY

The urethral pressure profile is commonly measured during normal bladder storage and provides information regarding the functional status of the urethra. Most commonly, these measurements are obtained under nonvoiding conditions with the urethra at rest, which is sometimes referred to as the resting urethral pressure profile. However, dynamic measurements may also be obtained during coughing (stress urethral pressure profile) and voiding (micturitional urethral pressure profile) to obtain functional information regarding the urethra during these conditions. Due to the multifactorial nature of this test, it is best to recognize the standardized terminology as it relates to the techniques of UPP being discussed, and the terminology that has been recommended by the International Continence Society is listed in Table 33.2 [39].

Table 33.2 ICS Terminology for UPP Testing

Urethral pressure measurements

Urethral pressure: The fluid pressure needed to just open a closed urethra

Urethral pressure profile: A graph indicating the intraluminal pressure along the length of the urethra

Urethral closure pressure profile: The subtraction of intravesical pressure from urethral pressure

Maximum urethral pressure: The maximum pressure of the measured profile

Maximum urethral closure pressure: The maximum difference between the urethral pressure and the intravesical pressure

Functional profile length: The length of the urethra along which the urethral pressure exceeds intravesical pressure in women

Pressure transmission ratio: The increment in urethral pressure on stress as a percentage of the simultaneously

Abbreviations:ICS, International Continence Society; UPP, urethral pressure profilometry.

Technique of Urethral Pressure Profile

The most commonly utilized methods of urethral pressure measurements are derived from the techniques introduced by Brown and Wickham [40]. This is the most commonly utilized technique to measure urethral pressures. The basic principle of this technique is the measurement of pressure needed to perfuse a pressure-sensing catheter at a constant rate. Thus, it measures the occlusive pressure of the urethral walls by recording the fluid pressure required to *lift* the urethra off the catheter. The catheters are optimally less than 10 Fr in size and contain two opposing side holes, which are some distance from the catheter tip. This can be done using a double- or triple-lumen catheter with separate lumens for recording bladder and urethral pressure. The urethral port of the catheter is connected to a pressure measuring transducer and a motorized syringe pump (usually via a “Y” connector). Constant perfusion at a rate of 2 mL/min to 5 mL/min is maintained. The catheter is then withdrawn at a rate of less than 5 mm/s in order to achieve satisfactory measurements. This may be accomplished manually or more precisely by a mechanical *puller* device (Figure 33.9). Other catheter types can be utilized to measure urethral pressures at rest. Microtransducer tip catheters may be employed. These catheters have the advantage of better resolution and accuracy when compared to perfusion catheters. However, they are expensive, require sterilization, and, most importantly, are prone to rotation artifacts within the urethra. The position of the transducer in the urethral lumen greatly effects the urethral pressure measurements. Balloon catheters have also been utilized. These catheters consist of fluid-filled balloons over the side holes, and the urethral pressures represent the average pressure measured over the length of the entire balloon. This design leads to many distortions in pressure measurement. When a catheter holding a transducer is within the urethra, it is reading the force generated by the walls of urethra, which are not equal in the 360° of the long axis. It has been found that pressures can range from the uppermost range to the lowest by changing the direction of the microtransducer from anterior to posterior. Catheter sizes between 8 and 12 French have been shown not to affect study parameters. This is not the case for bladder volume and patient position, as the pressure within the urethra goes up with increasing volume within the bladder and with a more upright stance. A comparison of air-charged and microtransducer catheters in the evaluation of urethral function showed high concordance for maximum urethral closure pressure (MUCP) and VLPP, but not for functional urethral length [41].

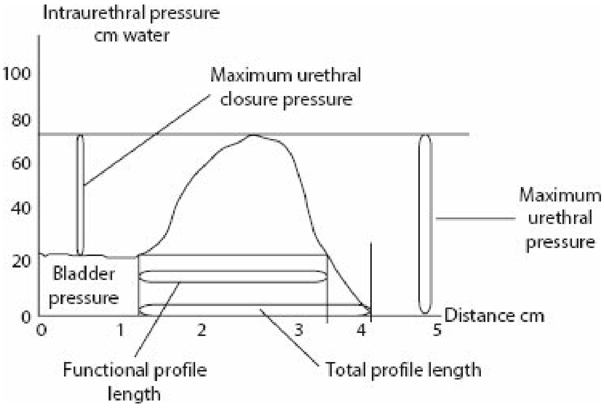

Figure 33.9 Urethral pressure profile: Note the individual parameters of the urethral pressure profile and the relationship to intravesical pressure. (Reproduced from Winters JC and Appell RA, Practical urodynamics, in O'Donnell, P.D., ed., *Urinary Incontinence*, Mosby, New York, 1997, pp. 181–189. With permission.)

The resting urethral pressure profile is usually performed supine. The bladder contains at least 50 mL, and the baseline bladder pressure is recorded. The catheter is then withdrawn at a constant rate (<5 mm/s) and the catheter is perfused at 2 mL/min. Continuous urethral pressure measurement occurs as the catheter is withdrawn, and these measurements should be made with the bladder at resting pressure [42]. The resting urethral pressure profile will produce a characteristic curve. In addition, the urethral pressure measurements can be taken at a fixed site in the urethra by securing the catheter with the urethral pressure sensors in the desired location. This is done fluoroscopically, or by using the measuring landmarks on the catheter. The stress urethral profile is performed in a similar manner. However, during the stress UPP the patient is asked to cough at regular intervals during catheter withdrawal. Alternatively, one may position the catheter at fixed sites along the urethra (0.5 cm intervals) while the patient coughs or performs a Valsalva maneuver. This method of urethral pressure measurement purportedly records the efficiency of pressure transmission into the proximal urethra. The major limitation of stress profilometry is that stress testing can move the profile catheter along the urethra, leading to misleading findings.

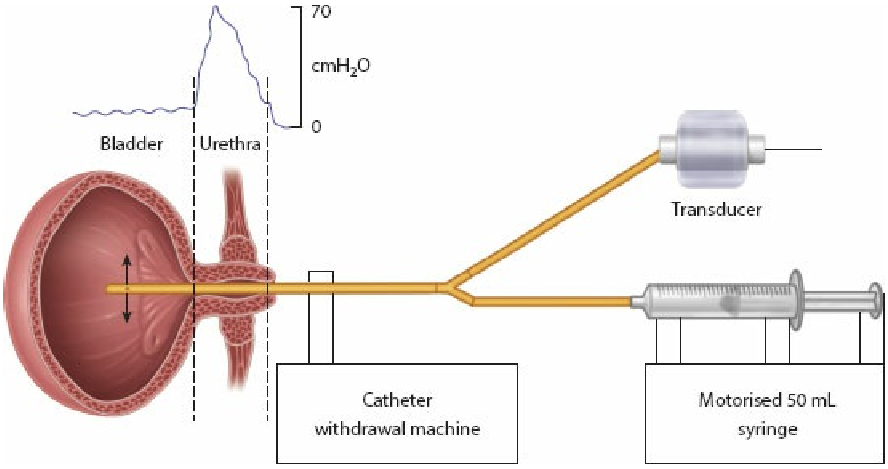

Figure 33.10 Brown–Wickham technique of urethral pressure measurement. (Reproduced from Abrams P, ed., *Urodynamics*, 3rd ed., Springer-Verlag, London, U.K., 2006, pp. 98–110. With permission.)

The catheter withdrawal technique as described generates an infusion profile curve representative of the UPP (Figure 33.10). The parameters obtained are defined by the International Continence Society [19] as

- P_{ves}, the pressure measurement within the bladder.
- Maximum urethral pressure (Pura), the highest pressure obtained during catheter withdrawal.
- UCPmax or MUCP, the difference in pressure obtained when P_{ves} is subtracted from Pura (which represents the pressure gradient from the urethra to the P_{ves}).
- Functional urethral length is the urethral length where the intraurethral pressure exceeds the bladder pressure.
- Total urethral length is the entire length of the urethra as measured using the withdrawal technique.

Thus, urethral length has two aspects, an anatomical one where it is the complete length of the urethra and the functional length, which is the distance of the urethra where urethral pressure exceeds the pressure found within the bladder [43].

Interpretation of Urethral Pressure Profile

In most continent women, the functional urethral length is approximately 3 cm and the MUCP is 40–60 cm water, but there exists considerable variability between studies [44]. It has been suggested that UPP can be helpful in women undergoing stress incontinence surgery. Through the early works of McGuire and Sand, patients with urethral closure pressures less than 20 cm water were noted to have higher failure rates of their incontinence repairs [43,44]. These findings have been supported by other studies showing that a low MUCP is a predictor of poor outcomes for retropubic suspension surgery [45,46]. These findings led surgeons to utilize sling procedures as the anti-incontinence procedure of choice for patients with low urethral closure pressure [47,48]. This change in practice must be taken in the context of a strong trend toward sling procedures (particularly midurethral slings) for all cases of stress incontinence, with or without low urethral pressure, which makes the UPP increasingly irrelevant to the choice of surgical procedure [49]. Weber demonstrated the inherent problems in utilizing UPP measurements in the diagnosis and management of SUI. She pointed out the significant variability within the reported values of urethral pressure measurements [49]. Differences in pressure measurements were seen with different types of catheters, varying positions of the catheter within the urethra, patient position, bladder volume, and the presence of POP. In addition, detrusor overactivity can affect urethral function resulting in decreases in functional urethral length and pressure transmission ratio (PTR) with bladder filling [50]. Although the investigator can control technical factors, there are still substantial differences in interoperator and per patient reproducibility. These factors account for widespread differences in reported values across urodynamics laboratories. As one examines the reported values of urethral pressure among investigators, there is considerable variability between investigators with the MUCP varying from 36 to 101 cm water in non–stress incontinent patients. In addition, there are large standard deviations of reported data, suggesting significant variability within the reported values [49]. Despite these differences however, there is a trend among studies that the urethral closure pressures are lower in stress incontinent women. However, in many of these studies, the differences are not statistically different and the overlap is so great that it is impossible to select a cutoff value that discriminates continent and incontinent patients [49].

If the urethra and the bladder were thought of as a continuous system free of the muscular activity that surrounds it, then the PTR can be thought of as the sequential increase in urethral pressure during a concurrent increase in bladder pressure [42]. This proportion can exist at a solitary location, or several points can be determined at distinct locations to produce a pressure transmission profile. Although it has been reported that stress incontinent women with urethral hypermobility generally have lower PTRs than stress continent women [51], other studies have questioned the validity of pressure transmission profiling, and the value of this test has been called into question [52]. The PTR also cannot discriminate between stress incontinent patients and controls [53]. As a result of such divergent data, the ICS has stated that the clinical utility of urethral pressure measurement is unclear [54]. Given the fact that UPP deals with urethra in a nonphysiological state of rest, it provides little information regarding incontinence as a result of anatomic derangement. Furthermore, no single parameter of the UPP is useful in diagnosing stress incontinence [55]. These reports have prompted the International Consultation on Incontinence Committee on Dynamic Testing to make the following recommendations regarding UPP [56]: First, investigators and clinicians should recognize the poor sensitivity and specificity of urethral pressure measurements and their normal test–retest variation. In addition, the committee does not recommend urethral pressure measurements as the only urodynamic test of incontinence. If performed, these measurements should be judged in relationship to other elements of the examination.

In conclusion, the clinical role of urethral pressure and the urethral closure pressure is questionable as there is no urethral pressure measurement that can discriminate urethral incompetence from other disorders, provide a measure of the severity of the condition, or provide a reliable indicator of surgical success after intervention [56]. Although attempts have been made to correlate a low MUCP with the presence of stress incontinence and with the presence of ISD (MUCP < 20 cm H_2O), the test proves to lack both sensitivity and specificity. Additionally, there are many continent women with low MUCPs and conversely incontinent women with a high MUCP [57]. To date, the preponderance of evidence demonstrates that the diagnostic accuracy of the urethral pressure profile is poor. This test, if utilized, should be interpreted in the entire clinical context of SUI in order to assess incontinence severity and not as a stand-alone evaluation of urethral function [54].

ELECTROMYOGRAPHY

Electric activity produced by a cell is a result of the interaction of various ions of opposing charge separated by a lipoprotein bilayer. Unequal distributions of ions on either side of the bilayer cause a gradient that leads to a difference in electric potential across the membrane. The motor unit is comprised of an anterior horn cell, its axon, and terminal branches (all of which make up the motor neuron), the neuromuscular junctions, and all the individual muscle fibers the cell innervates. The size of the motor unit, that is, the number of muscle fibers innervated by a single anterior horn cell, varies with each muscle. In general, muscles exhibiting fine motor control have low innervation ratios (e.g., 10 to 20:1 in the extraocular muscles), whereas big, bulk-supporting muscles have high innervation ratios (e.g., 1500 to 2000:1 in the gastrocnemius muscle) [58]. When an anterior horn cell is activated, all muscle fibers belonging to that motor unit are depolarized, and the electrical activity from these muscle fibers summate to generate a motor unit action potential (MUAP) [59]. Such activity produces a characteristic triphasic wave with distinct components, detectable by an electrode placed in close proximity. There is a positive (downward) deflection as the electrical impulse moves along the muscle fiber membrane toward the extracellular recording electrode. This is then followed by a negative (upward) deflection when the impulse reaches the electrode. Finally, another positive (downward) deflection results as the impulse moves away from the electrode (Figure 33.11). There are numerous types of electrodes, broken down into two distinct groups—surface and needle electrodes, all having their positive attributes, as well as negative characteristics.

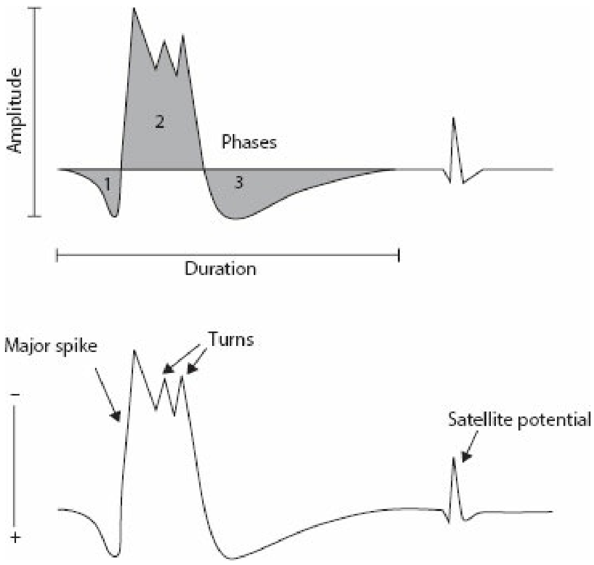

Figure 33.11 Duration is measured as the time from the initial deflection of the MUAP from baseline to its final return to baseline. It is the parameter that best reflects the number of muscle fibers in the motor unit. Amplitude reflects only muscle fibers very close to the needle and is measured peak to peak. Phases (shaded areas) can be determined by counting the number of baseline crossings and adding 1. MUAPs are generally triphasic. Serrations (also called turns) are changes in direction of the potential that do not cross the baseline. The major spike is the largest positive-to-negative deflection, usually occurring after the first positive peak. Satellite, or linked, potentials occur after the main potential and usually represent early reinnervation of muscle fibers. (Reproduced from Preston DC and Shapiro BE, *Electromyography and Neuromuscular Disorders*, Butterworth-Heinemann, Boston, MA, 1998, pp. 541–560. With permission.)

Skin patch electrodes are usually self-adhesive and have the benefit of being less invasive, with a patch being placed on the perineum. However, some contend that the signal may be inferior [60]. In preparation for a study using such electrodes, the skin should be shaved and prepared with alcohol to reduce surface resistance and the electrode placed directly on the skin overlying the muscle of interest [61]. With surface electrodes, EMG pattern recordings depict the net electrical activity occurring in the muscle. Surface electrodes therefore demonstrate an electronically generated summation of muscular electrical activity but are incapable of distinguishing individual motor unit potentials. This can be seen in the area of the striated urethral sphincter and levator ani, which are located in close proximity, but anatomically and neurologically discontinuous [62]. Thus, such perineal surface measurements may not reflect the true striated sphincter activity, but rather compounding of motor unit signals from all the muscles of the pelvic floor. In a comparison of patch vs. needle electrodes during pressure flow studies, needle electrode EMG was more often interpretable and showed motor unit quiescence of the external sphincter more often, suggesting that the signal obtained from the pelvic floor musculature in the region may mask the actual signal obtained from the external sphincter [63]. Needle electrodes are able to isolate electrical activity from specific muscle fibers within a 0.5 mm radius of the tip [63]. Such accurate information of course does come with a drawback of being more invasive and operator dependent.

Needle electrodes can be either monopolar, concentric, or single fiber in type varying in dimensions and the type of metal that is used. Monopolar electrodes are thin needles coated with an insulating material that have an exposed tip. A reference electrode is needed, such as a surface stick or subcutaneous needle attached to the skin near the muscle being examined. Concentric electrodes have a hollow cannula serving as the reference electrode. An insulated fine wire extends through the cannula exiting as a beveled tip and is the active electrode. The advantage of concentric electrodes is a more predictable surface area, producing more reliable measurements of MUAPs [64].

To obtain representative EMG studies of the pelvic floor, electrodes may be placed into the bulbocavernosus muscle through the perineum in men and the superficial anal sphincter in women. In women, the superficial anal sphincter is accessed with an electrode placed through the perineum at the 12 o’clock position, which is advanced just under the skin at the mucocutaneous junction to obtain an

EMG signal [65]. To obtain activity of the external urethral sphincter in women using these types of electrodes, a needle is placed lateral to the urethral meatus and advanced parallel to the urethra to a distance of about 1–2 cm. This of course may be difficult and painful for women, and meticulous attention to detail is required. The technical precision of needle placement is important in order to accurately record the activity within the true urethral sphincteric complex. If localized properly, *noise* from the adjacent pelvic floor can be eliminated, resulting in a true measurement of isolated sphincter function.

Normal EMG findings imply a lack of neurological basis for a patient's voiding dysfunction, whereas an abnormal EMG study indicates a need for further work-up. Findings must be taken in relation to the subject's concurrent action. In patients free of pathology, the EMG activity is low at rest, and it increases in amplitude and frequency with increases in pressure of the abdomen, such as coughing, laughing, and with bladder filling [60].

Due to the complex neurophysiological process of micturition, there is synergic coordination of the urethral sphincter mechanism and bladder. During voiding, the urethra should be relaxed, so as to permit the passage of urine. Focused EMG studies utilizing surface or needle electrodes can be carried out on the distal sphincter of the urethra. During a void, the urethra should be in a relaxed state, which would correspond to silence on the EMG, whereas during filling an increase in electrical activity should be observed [66]. The goal of EMG during UDS is to determine whether the external urethral sphincter complex is coordinated or uncoordinated with the bladder during voiding [67]. During the study, the absence of urethral relaxation during a void may signify an abnormality in urethral function. Such an abnormality in the context of a known neurological condition is termed detrusor external sphincter dyssynergia [68]. However, constant urethral tension during voluntary micturition in the absence of known neurological pathology is called dysfunctional voiding, which may represent a learned behavior [15].

EMG: Clinical Interpretation

Urethral sphincter EMG is used to make the diagnosis of DESD, and it is used to distinguish the 3 types of DESD (Figure 33.12). In type 1 DESD, there is a sudden and complete relaxation of the striated sphincter at the peak of the detrusor contraction, and unobstructed voiding occurs. Type 2 DESD is characterized by sporadic involuntary contractions of the striated sphincter throughout the detrusor contraction. Voiding occurs in bursts during sphincter relaxation. With type 3 DESD, there is a crescendo–decrescendo pattern of sphincter contraction, which results in urethral obstruction throughout the entire detrusor contraction. In all 3 types of DESD, the involuntary sphincter contraction precedes the involuntary detrusor contraction. In contrast, with AVD, the sphincter EMG activity diminishes just prior to the detrusor contraction and then sporadically increases as the patient contracts and relaxes the striated sphincter (Figure 33.13). The 2012 AUA Guidelines on Adult Urodynamics recommend that EMG be performed with cystometrogram in patients with relevant (at risk for upper tract complications) neurological disease at risk for neurogenic bladder, or in patients with other neurological disease and increased postvoid residuals or urinary symptoms.

Figure 33.13 Acquired voiding dysfunction. An involuntary detrusor contraction is heralded by complete relaxation of the sphincter electromyography (EMG). As the patient senses the detrusor contraction, she contracts her sphincter (increased EMG activity) in an attempt to prevent incontinence (arrows A). Once the sphincter fatigues, the urethra opens and incontinence ensues (arrows B). *Abbreviations:* EMG, electromyography; P_{ves}, intravesical pressure; P_{abd}, abdominal pressure; P_{det}, detrusor pressure. Fowler syndrome was first described in 1985 in young women with urinary retention [69]. The sphincter EMG signal in these women contains repetitive discharges and decelerating bursts. This impairs sphincter relaxation and leads to obstructed voiding with either incomplete emptying or retention. The development of the sphincter abnormality may be under the influence of estrogens, as suggested by the high association of polycystic ovaries in these women [70]. Sacral neuromodulation has a rapid effect in restoring voiding function in some of these women, which may work by reversing the inhibitory effect of the sphincter contraction on the voiding reflex. The abnormalities of sphincter function (abnormal EMG activity and high MUCP) are not reversed with neuromodulation [71].

It is clear that EMG measurements (particularly patch EMG technique) are nonspecific *generalizations* of sphincteric function. In essence, these studies represent an assessment of pelvic floor activity to determine if the appropriate relaxation/coordination in function is present. As in all urodynamic tests, these findings must be taken in global context, including history and physical examination (neurological disorder or not), fluoroscopy ("spinning top" appearance of the posterior urethra), and urinary flow to correlate the EMG activity to the other urodynamic events. These studies are not to be interpreted in isolation. Needle EMG may provide more precise detail regarding sphincteric activity, but patient discomfort appears to greatly restrict its use.

Urethral pressure reflectometry is a technique that uses the acoustic patterns detected in a polyurethane bag placed in the urethra, enabling measurement of the pressure needed to open the closed urethra and giving estimates of pressure and cross-sectional area in the entire length of the urethra [72,73]. The procedure appears to be less uncomfortable than conventional UPP and provides a more detailed and flexible approach to assessing various parameters of urethral function [74]. Reflectometry indicates that urethral opening pressure at rest is unchanged after TVT and that TVT brings increased resistance against the dilation of the urethra [75]. The technique is comparatively new and continues to be subject to ongoing improvements in methodology [76,77].

SUMMARY

The 2012 AUA Guidelines on Adult Urodynamics recommend urethral function tests (ALPP and/or UPP) in women who are undergoing urodynamics for the evaluation of SUI. In addition, EMG studies are recommended in patients with certain neurogenic disorders. These tests are not standardized in technique, are nonspecific, and lack diagnostic accuracy. In 2013, the International Consultation on Incontinence Research Society performed a critical assessment of the techniques of urethral function measurements and reached several notable conclusions. First, it was noted that the severe limitations of urethral function testing techniques confound a proper assessment of a fundamental element of maintaining continence. Second, there is a considerable gap between symptomatic realities we need to address in practice and the variables that our current tests can assess. Lastly, the significant need for research in improving our assessment of urethral function was noted [78].

Clearly, there is a need for better diagnostic accuracy in measuring urethral function. Whether it is through improvements in existing technology or emerging new technologies is yet unclear. What is clear is that the assessment of urethral function is through a comprehensive assessment including history and physical examination, diary assessment, and multiple urodynamic testing techniques (if needed). Urethral function tests are only one component of a comprehensive urodynamic examination and should not be used in isolation to obtain a diagnosis of urethral dysfunction.

34 Special Urodynamic Tests: Videourodynamics

Ilias Giarenis and Marcus J. Drake

INTRODUCTION

Urodynamics (UDS) is the umbrella term for any test giving a dynamic evaluation of lower urinary tract (LUT) function. The test in most widespread use is cystometry, in which abdominal and bladder pressure are measured synchronously with urine flow during bladder filling (filling cystometry) and voiding (pressure flow studies), as described in Chapter 32. Conventional UDS is informative in well-defined circumstances, but many women have additional complications in their symptomatology or past medical history. This can make the ability to obtain extra information important for full insight into underlying pathophysiology and consequently for making safe treatment recommendations.

Videourodynamics (VUDS) allows synchronous imaging during cystometry, and this enables the urodynamicist to elicit additional information at crucial times during the test. Cystometry was first synchronized with cinefluoroscopy in the early 1950s through the pioneering efforts of ER Miller [1] and further developed through the 1960s in the United States by Tanagho [2] and in the United Kingdom by Turner-Warwick [3]. Improvements in imaging technology, pressure transducers, digital signal processing, and computing have led the evolution of the original technique to the modern VUDS. The term videocystourethrography can be used interchangeably and is used in the most recent joint International Urogynecological Association/International Continence Society (ICS) terminology document [4]. VUDS is also referred to as fluorourodynamics mainly in North America.

While VUDS offers the most comprehensive means of assessment of LUT dysfunction, it constitutes a comparatively small proportion of urodynamic testing overall (6% in a cohort of 1.4 million female U.S. Medicare beneficiaries) [5]. Nevertheless, it is an essential measure for assessing complex cases by adding high-resolution anatomical details to the physiological (urodynamic) data. VUDS allows direct observation of the effects of bladder events, the position and conformation of the bladder neck in relation to the pubic symphysis, bladder neck closure during rest and stress, diverticula of the bladder and urethra, vesicovaginal and urethrovaginal fistulae, vesicoureteric reflux, and voiding events [4]. The current chapter describes how VUDS is undertaken, placing emphasis on the additional requirements and technique alterations compared to simple cystometry. The indications and limitations for VUDS are outlined, and the potential risks and benefits of gaining further insight into individual cases are discussed.

SPECIFIC REQUIREMENTS FOR VUDS

The ICS defined best urodynamic practice in a standards document published in 2002 [6], and, more recently, the Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction published relevant guidelines [7]. The ICS document states that a good urodynamic practice comprises three main elements:

1. A clear indication for, and appropriate selection of, relevant test measurements and procedures
2. Precise measurement with data quality control and complete documentation
3. Accurate analysis and critical reporting of results

Specifically for VUDS, a typical arrangement includes a fluoroscopy unit with an image intensifier, a multichannel urodynamic recorder, and a flowmeter. Some companies offer special equipment where computerized systems mix urodynamic signals with x-ray images in order to produce a combined superimposed image on a computer screen.

Fluoroscopy is performed using either a fixed x-ray unit with a table that can be positioned in the supine and upright position or a C-arm image intensifier. In fixed units, a radiotranslucent commode seat attachment to the table facilitates fluoroscopic screening of voiding in the seated position, which is ideal for women. While a C-arm image intensifier provides inferior image quality to fixed x-ray units, it enables patients to sit or stand in a natural position, ensuring the least inhibition to voiding. The use of a C-arm gives also some independence from the x-ray department and the ability to create a less daunting atmosphere, by performing VUDS in a purpose-built urodynamic suite [8]. Provision of a suitable environment is crucial, stipulating that the walls of the screening room are not permeable to x-rays, to ensure radiation does not spread into the adjacent environment. The VUDS room has to have suitable alerts when radiological screening is being undertaken, such as illuminated alert screens at the doorway when screening is happening to avoid unexpected entry of unprotected individuals into the x-ray environment.

Since the study is a radiological procedure, there are several key safety aspects, in addition to the preparation for conventional urodynamic tests:

- Steps should be taken to ensure radiation exposure of pregnant women is avoided.
- Women with prior allergic reactions to radiological contrast medium or iodine should be excluded.
- Compliance with national and international ionizing radiation medical exposure regulations.

For protection of patients, it is necessary to ensure there is adequate justification for doing the test, checking of patient identity, and screening mechanisms for pregnancies and allergies. Within the unit, a specific person has to take responsibility for compliance with the required legislation and ensure equipment maintenance is undertaken according to the manufacturer recommendations. All the urodynamicists should attend a structured radiation protection course and clinical skills, and competencies need to be assessed following training under an identified preceptor with a minimum of 40 cases and regular attendance at videourodynamic clinics and multidisciplinary meeting (MDM) relevant to the clinical areas covered [9].

Contrary to conventional cystometry, where the fluid used is saline, VUDS requires the use of radiological contrast medium for bladder filling, so that the bladder can be visualized with x-ray imaging. A low-concentration, low-osmolality nonionic contrast medium (e.g., Iohexol, Omnipaque^{TM} 140, GE Healthcare) is ideal for VUDS. As the contrast medium is of different density from urine, adjustments may have to be made to the flowmeter, which would otherwise record falsely high readings because of the greater weight of the voided fluid [8].

Every attempt should be made to minimize exposure to an “as low as reasonably achievable” (ALARA) level without sacrificing the diagnostic accuracy of the examination. A number of radiation exposure reduction techniques could be applied using the ALARA principles. The performance of fluoroscopy by trained urodynamicists allows tailoring of the examination to patient symptoms and past medical and surgical history and limiting parts of the examination that are not expected to offer valuable information, such as prolonged imaging during the voiding phase. Pulsed or low-dose setting continuous fluoroscopy with spectral beam filtration and optimal selection of the tube current and high voltage by an automatic brightness control system could further reduce the radiation exposure [10]. Minimization of the primary radiation field to include only the anatomical region of interest and an attempt to spare the ovaries also reduce the detrimental risks [11].

Staff also need to be protected, with x-ray-opaque (lead) aprons or shielding and body-worn dose monitoring detectors. During screening, all individuals present need to move to a location as far as practicable from the x-ray source and the source of scattered x-rays (notably the patient receiving the x-rays will scatter part of the dose). Indeed, remote monitoring from outside the room is increasingly realistic.

BASIC PRINCIPLES OF VUDS

When commencing a cystometry appointment, the urodynamicist needs to review the clinical presentation, treatment received thus far, medical history, and physical examination findings. The patient’s symptom scores and bladder diary are reviewed, so that the crucial aspects are clearly understood. Thereby, the urodynamicist can ensure there is the best chance of understanding contributory mechanisms and potential adverse aspects, so that a treatment recommendation can factor in correction of causative factors and avoidance of complications.

Filling cystometry is performed according to the ICS standards [6]. Overall, the major distinctions of

VUDS from conventional UDS are the use of contrast as the bladder filling medium and the adaptations of the patient positioning. Positioning during filling and voiding has to be considered, in order to enable placement of the anatomical areas into the line of the imaging equipment.

Fluoroscopy is performed at key points as deemed relevant by the urodynamicist and depending on the urodynamic question:

- After filling with about 50 mL of contrast. This serves as a “baseline” for comparison with x-ray screening performed at other times.
- When the patient first reports sensation. This is used to assess whether the bladder neck has opened (since stimulation of urethral receptors can give a sensation of urgency) and whether the bladder has changed shape (suggesting the occurrence of bladder contraction).
- During stress provocation tests. Pelvic floor support is assessed by noting the position of the base of the bladder at rest and during the cough series or straining. At rest, it should be level with the pubic symphysis, and when straining, only a low-amplitude transient downward movement should be observed. Activating the imaging equipment for a short time (<2 seconds) allows the urodynamicist to assess the state of pelvic floor support (Figure 34.1) and observe the presence of stress urinary incontinence (SUI) (Figures 34.1 and 34.2).
- When the cystometric capacity is reached. It is performed to assess the bladder shape and outline and the presence of vesicoureteric reflux (VUR).
- During voiding to assess the urethral shape and outline. Screening during voiding should reveal a urethra of 2–3 cm length and an even caliber. The presence of proximal urethral dilation may indicate obstruction (Figure 34.3), and descent of the bladder base may indicate straining to initiate or maintain the urinary stream.
- During a voluntary stop test. An optional inclusion that can be performed to re-evaluate the presence of VUR.
- After completion of voiding to assess for residual contrast medium.

Screening is usually done in the anteroposterior and oblique plane, both during filling and voiding. Sometimes, other planes can be helpful in cases of suspected structural abnormalities. For example, a lateral viewpoint can be useful in mapping the location of a bladder diverticulum.

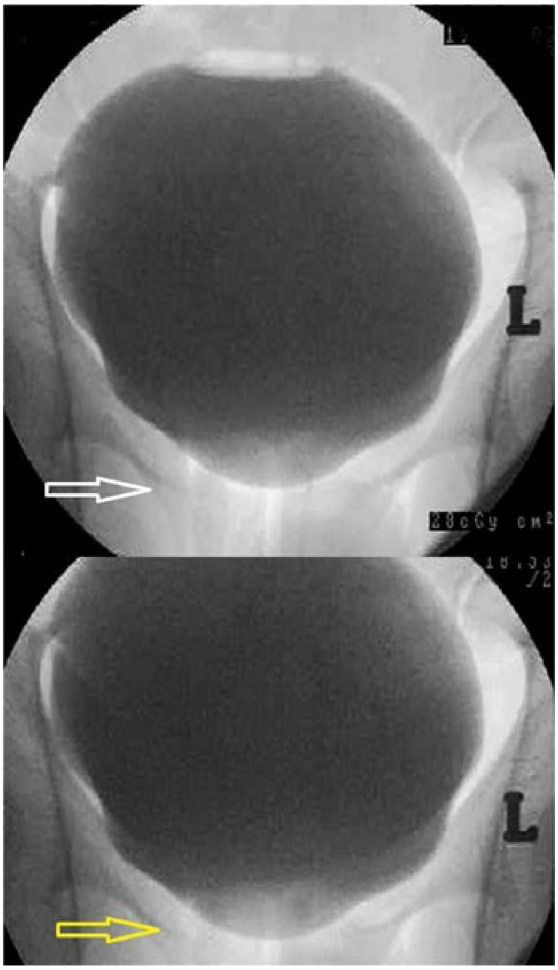

Figure 34.1 A woman with a well-supported pelvic floor. At rest, the base of the bladder lies slightly above the lower border of the pubis (upper image, white arrow). When she coughed (lower image), the bladder base was only fractional lowered at maximum cough amplitude (yellow arrow).

In a continent woman, only the bladder should fill, but contrast filling of other structures should be noted:

- *Urethra*: During the filling phase, urethral visualization suggests SUI.
- *Vagina*: Vaginal visualization indicates either that the bladder filling line was misplaced or displaced, vaginal pooling of contrast (due to dribbling or spraying stream, SUI, or perineal intrusion into the urinary stream) (Figure 34.4), or the presence of a vesicovaginal fistula (VVF).
- *Ureter*: During the filling or voiding phase, ureteric visualization indicates retrograde flow of liquid from lower to upper urinary tract, i.e., VUR (Figure 34.5).
- *Bowel*: A rare event that results either from a fistula or wrongly connected urodynamic lines.

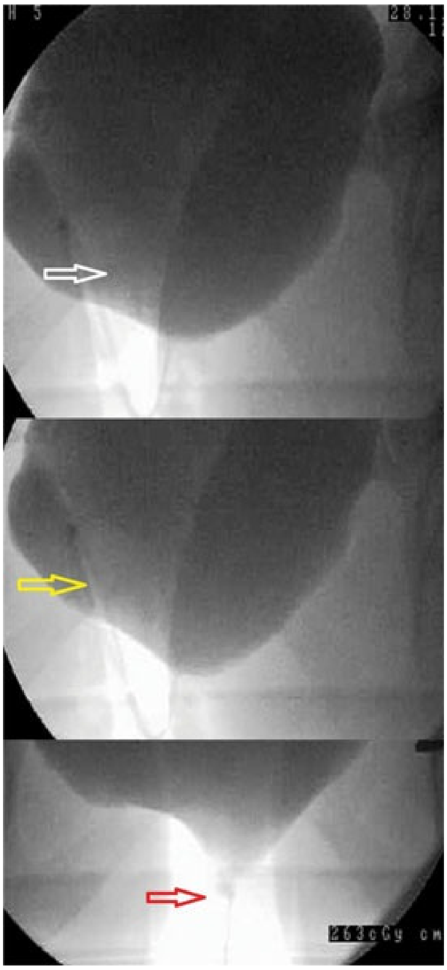

Figure 34.2 A woman with a poorly supported pelvic floor (anterior compartment POP). At rest, the base of the bladder lies below the lower border of the pubis (upper image, white arrow). When she coughed (middle image), the bladder base was further lowered at maximum cough amplitude (yellow arrow indicates base of pubis). With a series of coughs, urodynamic stress incontinence (bottom image, red arrow) was seen on the third cough.

WHO SHOULD UNDERGO VUDS

In most units, invasive evaluation is undertaken following full urological and gynecological assessment and conservative treatment. Only if refractory bothersome symptoms remain in a patient willing to undergo more interventional treatment would cystometry be undertaken. The specific urodynamic approach to understanding the patient's problems has to be derived from the clinical context and potential treatment options. While simple subtracted cystometry is usually sufficient in parous women complaining of primary SUI who have no major medical history of note, assumptions about responsible pathophysiology are not appropriate in other complex cases since there is a greater variety of potential mechanisms underlying. Use of VUDS is needed where the pathophysiology is difficult to predict.

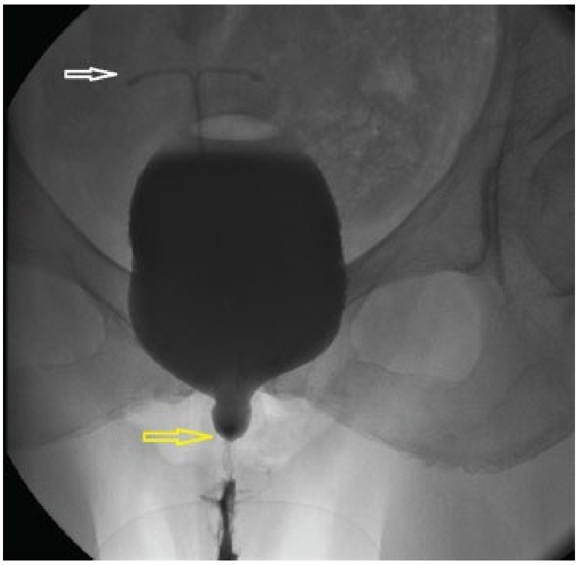

Figure 34.3 A woman with a previous midurethral tape operation, causing partial urethral obstruction (yellow arrow). Note the urethra is dilated proximally. An intrauterine contraceptive device is also present (white arrow).

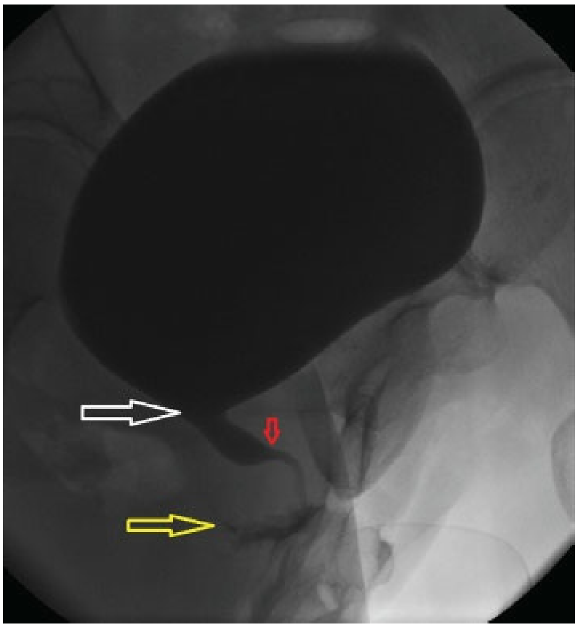

Figure 34.4 A woman with vaginal pooling of voided contrast (yellow arrow). The white arrow indicates a well-opened bladder neck. There is some sphincter contraction visible on this image (red arrow).

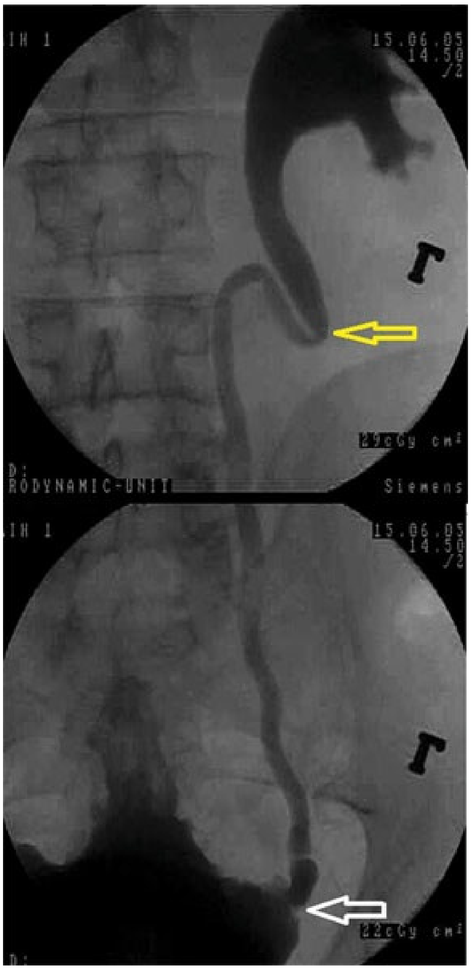

Figure 34.5 Vesicoureteric reflux (VUR). Contrast has passed retrogradely all the way to the kidney. The white arrow marks the ureterovesical junction. Chronic VUR is often associated with an abnormally tortuous proximal ureter (yellow arrow).

Due to the lack of robust scientific evidence, indications for VUDS are based on expert opinion. The International Consultation on Incontinence (ICI) [12,13], the American Urological Association [7], and the European Association of Urology (EAU) [14] have recently reviewed the available evidence and developed relevant guidelines. When available, VUDS should be considered:

- For women with relevant neurological disease at risk of neurogenic bladder (NGB) or in patients with other neurological diseases and elevated postvoid residual (PVR) or urinary symptoms (EAU, Grade of Recommendation A; ICI and AAU, Grade of Recommendation C)
- In the preoperative evaluation of women with persistent or recurrent UI after continence surgery (ICI: Grade of Recommendation C)
- For women with UI after complicated pelvic surgery and high suspicion for VVF
- In the assessment of women with complex incontinence where the history does not fit the findings on preliminary investigations
- For women with coexisting lower urinary tract symptoms (LUTS) and recurrent urinary tract infections in order to rule out structural anomalies [15]

WHAT INFORMATION CAN BE DERIVED DURING VUDS

During the filling phase, the following diagnoses may be identified:

- Urodynamic stress incontinence (USI) (Figure 34.2); this is defined as involuntary leakage of urine, associated with increased intra-abdominal pressure, in the absence of a detrusor contraction [4]. It can be a consequence of urethral hypermobility or intrinsic sphincter deficiency (ISD). The two often coexist but sometimes can be distinguished using VUDS, since USI from ISD is seen to arise with only minimal descent of the pelvic floor (Figure 34.6). ISD is an important possibility in women who have had previous pelvic or incontinence surgery and those with neurological disease. Distinguishing the type of USI is important since it may affect the chance of a successful outcome after operative intervention especially in the challenging group of women with persistent or recurrent USI after failed continence surgery [16]. VUDS is also more sensitive in detecting USI compared to conventional UDS as even minimal loss of contrast can be detected during screening [17].

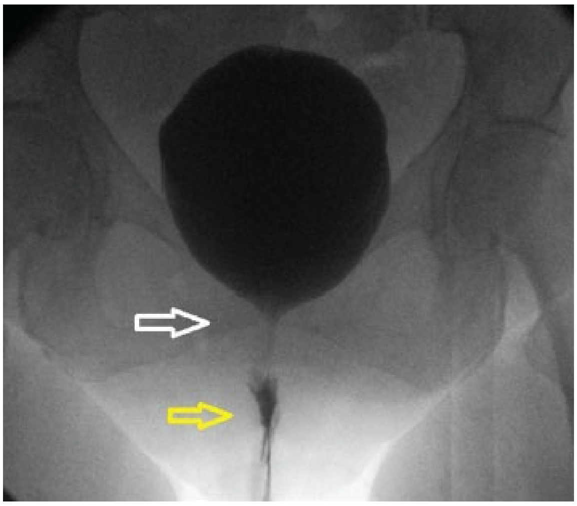

Figure 34.6 A woman with urodynamic stress incontinence caused by intrinsic sphincter deficiency. At rest, the base of the bladder lies level with the lower border of the pubis (white arrow). When she coughed, the bladder base did not move any lower and the urethra opened, i.e., stress incontinence (yellow arrow).

- Detrusor overactivity (DO): A urodynamic observation characterized by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked [4]. The presence of DO is routinely diagnosed from the pressure trace. However, in the presence of an incompetent urethral sphincter, a change of the bladder shape during VUDS might suggest the occurrence of a bladder contraction without simultaneous rise of the detrusor pressure.
- Increased filling sensation: Patients reporting urgency sensations where no DO occurs on the pressure trace may benefit from x-ray imaging during the urgency episode, as opening of the bladder neck or low-grade stress incontinence may be detected; the contact of urine on the urethral receptors can give a strong sensation.
- Structural abnormalities such as VUR (Figure 34.5), VVF, and bladder diverticula. Bladder hernias through the rectus sheath could be detected in women with multiple lower abdominal/pelvic surgery (Figure 34.7). Extrinsic pressure from pelvic masses (e.g., uterine fibroids, adnexal masses) might also be visualized (Figure 34.8).
- Quality of pelvic floor support: If poorly supported, the pelvic floor can bulge downward at rest or during a rise in abdominal pressure.
- Occult USI on prolapse reduction. Screening during VUDS can confirm successful reduction of a large cystocele after insertion of a pessary. This test has high specificity (93%) and negative predictive value (98%) in predicting SUI after prolapse surgery [18].

The following diagnoses may also be identified during or after the voiding phase:

- *Bladder outlet obstruction* (*BOO*). Voiding with high detrusor pressure but only a low flow rate indicates that there is an obstruction impeding urine flow. For women, there is no standardized diagnostic criterion for establishing BOO, despite the description of various approaches [19]. VUDS can be used to classify a woman as having partial BOO if there is radiographic evidence of obstruction between the bladder neck and distal urethra in the presence of a sustained detrusor contraction [20]. The location of BOO can often be seen clearly since the urethra proximal to the obstruction will typically be dilated (Figure 34.6). However, inclusion of urodynamic testing does not necessarily lead to influence on clinical outcomes of treatment, if voiding symptoms or retention is the reason for intervention [21].

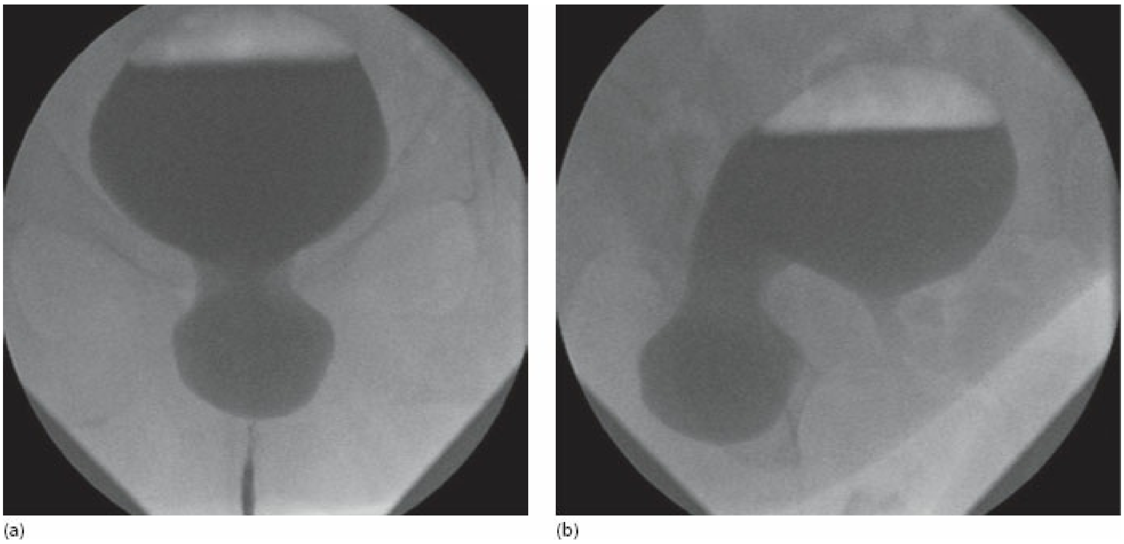

Figure 34.7 Bladder hernia through a rectus sheath defect in anteroposterior (a) and oblique (b) plane.

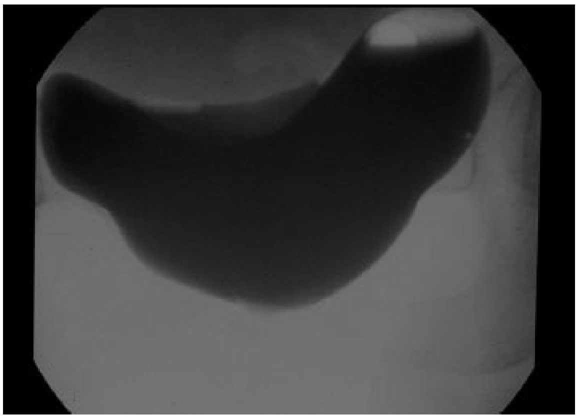

Figure 34.8 Extrinsic bladder pressure from a large fibroid uterus.

- Detrusor underactivity is a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span [4]. Detrusor underactivity is more prevalent in older women. VUDS can be useful as it helps exclude the presence of BOO.
- Dysfunctional voiding may be diagnosed if persistent sphincter contractions are seen during voiding in neurologically normal women; these can be visualized with VUDS. A similar picture of incoordination between detrusor and sphincter during voiding due to a neurological abnormality is suggestive of detrusor sphincter dyssynergia.
- Structural abnormalities such as urethral diverticula (Figure 34.9) and urethrovaginal fistulae.
- Incomplete bladder emptying: x-ray screening after the void can rapidly ascertain whether bladder emptying is complete or whether there is a “postvoid residual.” Particular care should be taken if there is a bladder diverticulum since a narrow neck may slow draining of the diverticulum, leaving contrast still present, even if voiding managed to empty the bladder efficiently. Care is also needed in the presence of VUR, as return of the refluxed contrast from the upper urinary tract to the bladder can falsely give the impression that bladder emptying was incomplete.

Overall, VUDS provides extra information, which could alter patient diagnosis and management. A case series in a tertiary referral center has shown that in 7.5% of patients, the correct diagnosis was made only with VUDS [17]. Especially in patients with NGB, it permits the diagnosis of abnormalities due to a variety of different neurological conditions and in some cases may help distinguish the etiology of NGB with respect to the underlying neurological disease [7]. Finally, video and sound recording allows review of complex cases during multidisciplinary meetings.

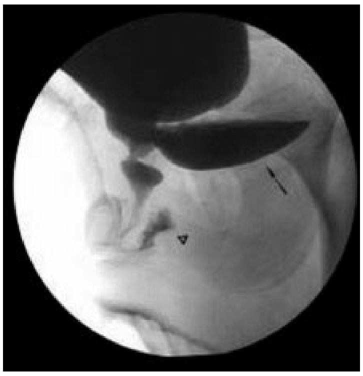

Figure 34.9 Urethral diverticulum filled during the voiding phase with typical air–fluid level (arrow). Contrast medium pooling in the vagina (arrowhead).

LIMITATIONS OF VUDS

Radiation

Although awareness of the radiation exposure from diagnostic radiology has been gradually increasing, there are limited data regarding the radiation effective dose of VUDS in the literature [22]. The variety of examination protocols has led to a wide range of reported radiation doses. The mean effective dose of VUDS varies between 0.34 mSv for a protocol using fluoroscopy only [23] and 4.3 mSv for a protocol requiring routine static image acquisition [24]. Among the organs, the bladder and uterus receive the highest absorbed doses with 1.57 and 1.39 mGy, respectively [24]. Based on the current ICRP recommendations (ICRP 103) [25] with a mean effective dose of 0.34 mSv, VUDS could result in approximately 1 in 75,000 cases of fatal cancer and have a total detriment risk (including fatal and nonfatal cancers as well as severe hereditary effects) of 1 in 50,000.

Despite the very low radiation risk, every attempt should be made to minimize exposure to an ALARA level without sacrificing the diagnostic accuracy of the examination. The decrease in the number of the voiding radiographs has been shown to reduce the radiation dose without compromising the quality of testing in VUDS [26]. A quality assurance protocol is also able to reduce the radiation exposure by decreasing the number of the spot films and fluoroscopy time [27]. Routine documentation of fluoroscopy time and dose area product by the urodynamicist is advisable as it raises radiation awareness and reduces the radiation dose [28].

Anaphylactic Reaction

Anaphylactic reaction is a recognized complication of administration of radiographic contrast media. Immediate severe reactions can lead to laryngeal edema, hypotension, and very rarely even death. After excluding women with a history of allergic reaction to contrast medium, the risk of an anaphylactic reaction due to contrast after VUDS is less than 0.01% [29]. Almost all reported cases of contrast reactions occur in the presence of Grade II or above VUR, as the urothelium forms an effective barrier against contrast absorption, whereas the renal pelvices may allow small quantities of contrast to enter the circulation [30]. In the absence of VUR, a reaction may still be possible if extravasation of contrast occurs following an injury to the urothelium. The selection of contrast agents might influence the anaphylactic risk as low-osmolality nonionic contrast medium is associated with lower rate of severe reactions than conventional high osmolar ionic agents (0.04% vs. 0.22%) after intravenous administration [31].

Other Factors

VUDS is more expensive compared to conventional UDS, as it is more time-consuming and requires the use of expensive equipment, along with the cost of contrast medium. It also requires operators with specialized training and adequate workload to maintain their competence [9]. Therefore, it is an investigation limited usually to large tertiary referral centers.

The quality of imaging may also be poor with obese patients and those with anatomic limitations to their positioning. It could also be difficult for some patients to void in front of the camera, with catheters in the bladder and rectum and observers watching them in an unnatural laboratory environment.

FUTURE DEVELOPMENTS

Alternative imaging modalities have been explored in light of concerns regarding x-ray radiation hazards associated with VUDS and the lack of soft tissue imaging. Two-dimensional and three-dimensional pelvic floor ultrasound offer supplementary information about bladder neck position and mobility, urethral sphincter volume, pelvic organ descent, morphology of the levator ani, diameters of the genital hiatus, and location and functional impact of a preimplanted tape [32]. However, simultaneous performance of ultrasound with cystometry is challenging. Standardization of pelvic floor ultrasound imaging and well-designed and adequately powered multicenter studies are required before its introduction into routine clinical practice.

Dynamic magnetic resonance imaging (MRI) offers an alternative option for imaging in patients with complex pelvic floor dysfunction [33]. Despite the advantage of the lack of radiation, MRI is an expensive investigation, not always available, requiring specialist radiological interpretation and cannot be performed with synchronous multichannel cystometry.

Due to the minimal data in the literature, there is an outstanding need to evaluate further the role of preoperative VUDS especially prior to redo surgery, with studies assessing how these tests influence decision making and/or improve surgical outcome [13]. Future prospective studies could also explore the diagnostic value of the different phases of VUDS and the associated radiation risk.

CONCLUSIONS

VUDS is a useful test for more complex cases in women who are still symptomatic after conservative treatment. Additional safety measures and training are needed compared with conventional UDS. Nonetheless, imaging can provide valuable anatomical and functional information relevant for decision making in individual cases.

35 Special Urodynamic Test: Ambulatory Urodynamics

Kevin L.J. Rademakers and Gommert A. van Koeveringe

INTRODUCTION

Urodynamic investigations are an important tool in the diagnostic route of patients with lower urinary tract (LUT) dysfunction. Apart from the generally used conventional urodynamic studies (conventional UDS), certain centers conduct ambulatory UDS additionally for specific indications. In contrast to conventional UDS, in which artificial filling is used, ambulatory urodynamic monitoring is based on diuresis-induced natural filling of the bladder [1]. Herewith, ambulatory UDS mimics the situation in which the patients have their urinary symptoms close to what they experience in real life. This is important as incontinence is a benign condition but can diminish quality of life significantly and can influence everyday life. In addition, the argument of conventional UDS being nonphysiological is bypassed by ambulatory urodynamics through the use of natural filling. Furthermore, the laboratory situation in which conventional urodynamics are performed can give psychological inhibition of the bladder [2].

Natural (orthograde) fill cystometry was described for the first time in 1957 by Comarr [3]. In 1959, Mackay [4] reported about bladder pressure measurement in an ambulant patient using radiotelemetry. In the first systems, telemetry was used [5,6]. The technique has evolved ever since, and many methods have been developed [1,7,8]. As time progressed, tape recording systems have been used, with the disadvantage of limited recording capacity [9]. In 1989, Griffiths et al. [10] developed an ambulatory system using microtip pressure transducers and a digital solid-state recorder. This made transfer of data and review of the data at the end of the assessment possible.

At present, ambulatory UDS is a reliable and well-tolerated cystometry tool. The technique is particularly valuable in recording bladder filling and voiding phases (Figure 35.1), combined with the amount and timing of urinary incontinence in a near-normal situation (Figure 35.2) [2,11–15]. This makes ambulatory UDS a useful tool in patients with troublesome urinary tract symptoms [1].

Despite the advantages of ambulatory UDS, conventional UDS is the “gold standard” for the investigation of LUT symptoms as it is a highly standardized and validated measurement tool [16,17]. Validation of ambulatory urodynamic monitoring has proven to be difficult. Validating a sensitive diagnostic tool (ambulatory UDS) based on a less sensitive gold standard (conventional UDS) is arguable. Therefore, validation of ambulatory UDS should be based on the correlation with patient-related treatment outcome. However, studies comparing ambulatory urodynamics to the patients’ treatment outcomes have not been described yet.

This chapter will focus on the indication and procedure of ambulatory UDS. In addition, the use of ambulatory UDS with respect to voiding and storage symptoms will be discussed [8,18,19].

INDICATIONS

- LUT symptoms that conventional UDS fails to reproduce or explain
- Overactive bladder syndrome without detrusor overactivity on conventional UDS
- Incontinence of unclear primary origin
- Voiding dysfunction without detrusor contractility on conventional UDS

EQUIPMENT

A guideline on urodynamic equipment performance was published by a specific International Continence Society (ICS) working group in 2014. This paper covers the technical aspects and considerations of urodynamic equipment. In this chapter, we will include relevant parts of these guidelines [20].

Ambulatory urodynamic equipment consists of an abdominal (usually rectal) and bladder pressure catheter (connected to a transducer system), a recording unit, and the analyzing system. The catheters generally used in conventional urodynamic measurements are water filled and connected to an external transducer. Water-filled systems respond reasonably well to fast pressure changes and are recommended by the ICS for the use in conventional urodynamics [16,21]. However, in ambulatory urodynamics, water-filled catheter systems are not recommended, as pressures measured are dependent on the patients' positioning and are prone to movement artifact [20].

Air-filled catheter systems are also mounted to an external transducer, with the difference that the catheter is filled with air instead of water. Because of the low density of air, the measured pressure is transmitted directly from the catheter tip to the transducer, making it functionally more similar to a catheter-tip transducer. However, responses to rapidly changing pressures can be delayed and diminished in air-filled catheter systems [21]. Air-filled catheters were used for ambulatory UDS in the 1980s [9]. However, based on the limited recording capacity available at that time, a recording threshold was determined. Consequently, small pressure differences were missed, and diagnosis based on the measurement could not reliably be provided.

Currently, microtip pressure transducers are often used for ambulatory UDS. In this system, the transducers are mounted in the tip of the five to eight French catheters inserted in the bladder and rectum. The catheter inserted in the bladder contains a second transducer measuring pressure at the urethral level. The registered pressure signal is converted to a voltage, which is then amplified. Compared to water-filled catheter systems, microtip transducers are less prone to movement artifact, with the additional advantage of fast response to pressure differences. A major disadvantage of microtip catheters is the positioning of the catheter tip since, like the air-filled catheters, there is uncertainty of positioning of the microtip transducers [20]. This can result in pressure differences between measurements. Therefore, pressure values should be clearly displayed at the start of the assessment. Microtip transducer drifting during the measurement can be an issue; however, this is usually only within a small range [22].

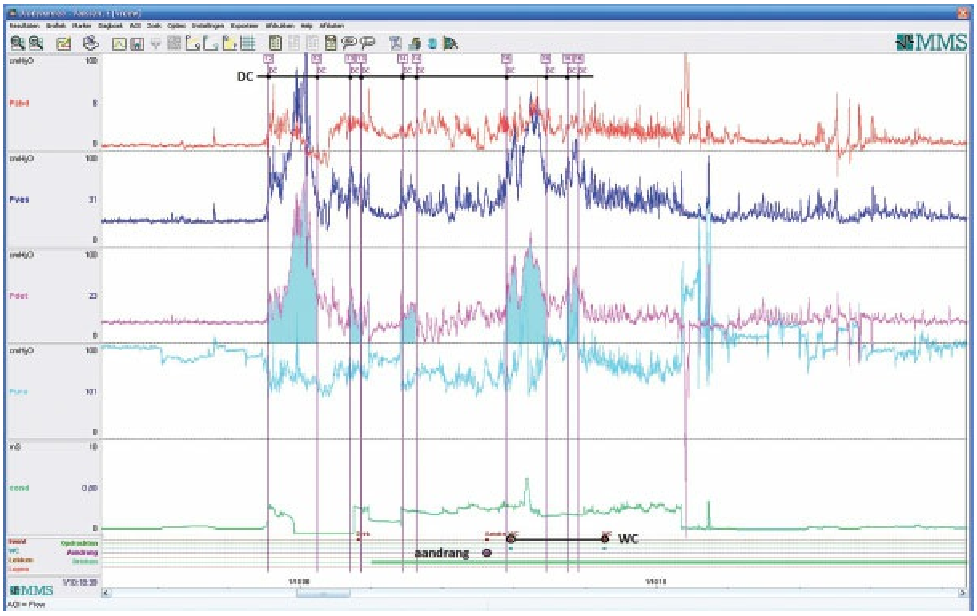

Figure 35.1 Ambulatory urodynamic trace showing detrusor overactivity (with high detrusor pressure), in the presence of the used "urgency" event button. "DC" marker: detrusor contraction, indicating the start and end of a detrusor contraction (detrusor overactivity if during the filling phase). "Aandrang" marker: represents the urgency event. "WC" marker: indicating start and end of the toilet visit.

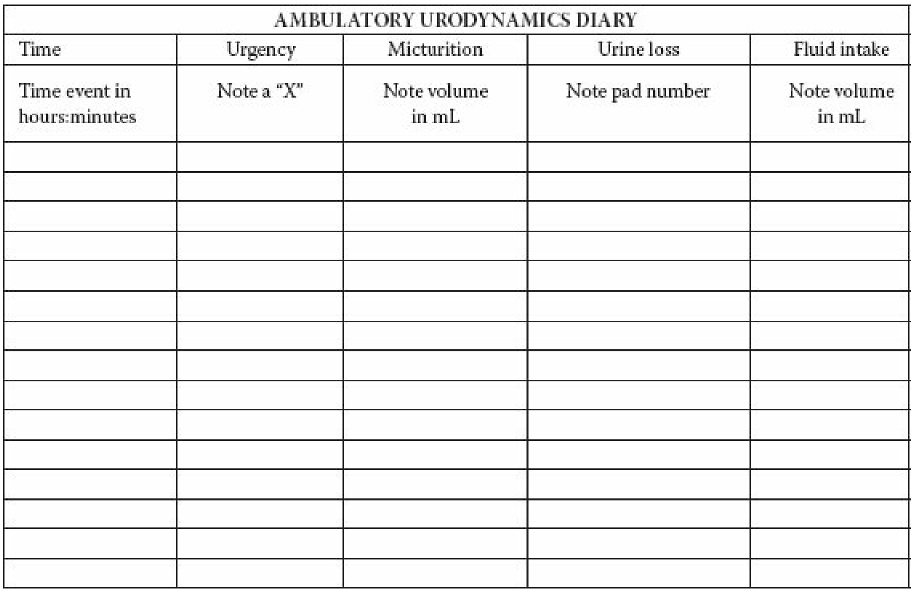

AMBULATORY URODYNAMICS DIARY				
Time	Urgency	Micturition	Urine loss	Fluid intake
Time event in hours:minutes	Note a "X"	Note volume in mL	Note pad number	Note volume in mL

Figure 35.2 Ambulatory urodynamic diary.

During ambulatory UDS, physiological signals and other behavioral indicator parameters are measured and stored in a portable digital recording unit. Currently, several comparable ambulatory urodynamic systems are available, including Luna (MMS), Blue Runner (Memphis), and Medkonsult's UroPress Salsa (information obtained April 2014). Besides recording pressure signals, the recording device contains several event buttons. Patients are instructed to use these buttons at specific events, for example, in case of an urgency episode, a toilet visit, drinking, or involuntary leakage of urine. At present, the registration of these events is connected to a timer incorporated into the recording unit. The event buttons should be simple and easy to interpret as event timings are essential for interpretation of the ambulatory UDS, along with urodynamic trace and detected urine leakage [1]. In patients needing to perform clean intermittent self-catheterization (CISC), an additional eight French catheter might be inserted via the urethra during the assessment. Postvoiding residual urine can then be drained after voiding attempts, in case of incomplete voiding.

Pressure traces are transferred to a computer and via specific software translated to a measure of detrusor and urethral function (Figure 35.1). Wireless Bluetooth techniques have the advantage of instant pressure–flow trace viewing while recording [23].

For evaluation of incontinence, urine loss measurement during ambulatory UDS is essential. There are several options for measuring urine leakage. First, the loss can be measured by using an electronic pad or electronic diaper (Urilos). The electronic pad has elongated, interleaved electrodes embedded in absorbent material. A 50 mV (low voltage) alternating current is passed between the two electrodes. The current increases as the urine loss increases, depending on the extent of contact between the electrodes and the conducting medium (urine). Because of this, the pad has to be preloaded with a known volume of electrolyte solution. The electronic pad is only suitable for volumes between 1 and 100 mL, which makes this method useful in only a proportion (20%) of the patients.

A second option is measuring perineal temperature. Urine has a higher temperature than that of the body surface. In case of urine leakage, the temperature steadily rises above skin surface temperature after which temperature rapidly falls. This allows urine loss episodes to be identified. The rate of temperature rise may correlate well with the amount of urine leaked. However, this measurement technique is dependent on the position of the detector in relation to the leaked urine as well as the position of the patient. Perineal temperature rises when a patient sits, meaning explicit instructions are necessary.

The third method is measurement of urine leakage by using a weighed pad. When used as a separate method, this test gives a rough estimation of the amount of urine that has been lost, but it gives little information about the timing of urine leakage. However, combining this with placing a conductance catheter gives the necessary additional information on the episode of urine leakage. A conductance catheter contains two electrodes and is placed within the urethra. A current is passed between both electrodes. In the event of urine passage, there is an increased conduction and a larger current passes across the electrodes. However, exact localization is key and should be monitored closely at the start of the assessment.

STANDARDIZATION OF AMBULATORY URODYNAMIC STUDIES

A standardization report on ambulatory UDS was published by a working group of the ICS in 2000 [1]. This document covers different aspects such as technical considerations and suggestions and both clinical and scientific reports for ambulatory urodynamics. In this chapter, we will discuss the parts of this report most relevant for clinical purposes.

Terminology

The ICS standardization working group advises the use of terminology during ambulatory UDS, which is consistent with that used during conventional UDS [24].

Methodology

Signals

The following signals are (have been) recorded by ambulatory UDS:

- Pressure: intravesical, abdominal, and urethral
- Flow rate
- Micturition volume
- Residual urine (e.g., with a bladder scan), in those cases where preassessment CISC was undertaken
- Urinary leakage episode
- Leakage volume
- (Urethral electrical conductance)
- (Perineal integrated surface electromyography)

Additional Event Marker Information

Event marker information should be recorded during any ambulatory UDS to include the following phenomena:

- Initiation and cessation of voluntary voids
- Episodes of urgency
- Episodes of discomfort or pain
- Provocative maneuvers
- Time and volume of fluid intake
- Time and volume of urinary leakage
- Time of pad change

Signal Quality

Ambulatory UDS is more versatile and represents a more natural situation compared to conventional urodynamics. The versatility of ambulatory urodynamics is associated with a greater risk of losing signal quality. Therefore, although all signals should be recorded as outlined in the ICS recommendations on “good urodynamic practices” [16], there are a number of cautions that apply specifically to ambulatory UDS, as described in the following text.

Intravesical and Abdominal Pressure Measurement

Although it is possible to measure intravesical and abdominal pressures using fluid-filled lines (water or air), the use of catheter-mounted microtip transducers allows greater mobility during ambulatory UDS. In the absence of continuous supervision, stringent checks on signal quality should be incorporated in the measurement protocol. At the start of monitoring, these should include testing of recorded pressure online by coughing and abdominal straining in the supine, sitting, and erect positions. The investigator must be convinced that signal quality is adequate before proceeding with the ambulatory phase of the investigation.

Prior to termination of the investigation, and at regular intervals during monitoring, similar checks of signal quality such as cough tests should be carried out. Such tests will serve as a useful retrospective quality check during the interpretation of traces. The following considerations must be taken into account when using microtip transducers:

- Transducers should be calibrated before every investigation.
- The “zero point” is atmospheric pressure. All transducers must be “zeroed” at atmospheric pressure before insertion of the catheters.
- Water-filled pressure catheters have a fixed reference point at the upper edge of the symphysis pubis, whereas catheter-mounted microtip pressure transducers have no fixed reference point.
- Microtip transducers will record direct contact with solid material (the wall of a viscus or fecal material) as a change in pressure. The use of multiple transducers may eliminate this source of artifact.
- Under some circumstances, the pressure measured at the transducer surface will result in a discrepancy equal to the difference in a vertical height between the two transducers. This can result in the estimated detrusor rest pressure being <0 (i.e., negative) with, for instance, the patient in supine position.

Urethral Pressure and Conductance

The recording of urethral pressure is a qualitative measurement with emphasis on changes in pressure rather than absolute values. The use of urethral electrical conductance to identify leakage in association with pressure monitoring facilitates interpretation of urethral pressure traces. Precise positioning and secure fixation of catheters are essential to maintain signal quality (Figures 35.3 through 35.5). The orientation of the transducer should be documented. (The use of multiple pressure transducers facilitates identification of movement artifact but increases catheter stiffness and thereby deformation of the urethra during recording.)

Catheter Fixation

Securing catheter fixation is essential to maintain signal quality. Methods that have been used include adhesive tape, suture fixation, and specially designed silicone fixation devices.

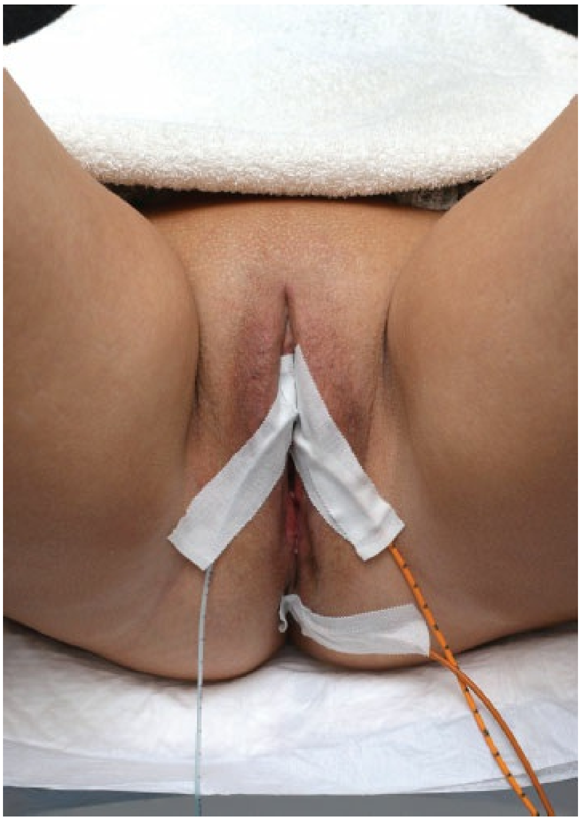

Figure 35.3 Positioning and fixation of the urodynamic catheters in a woman who is unable to void to completion. The blue catheter represents one to empty the bladder after micturition. The yellow catheter on the top is used for measuring intravesical and urethral pressures. The lower catheter, fixated to the buttock, is used to measure rectal pressure.

Recording of Urinary Leakage

The method of urine leakage determination should be recorded. It should be stated whether the urinary leakage is recorded as a signal with the pressure measurements or is dependent on the subject pressing an event marker button or completing a urinary or leakage weight diary (Figure 35.2).

Instructions to the Patient

Detailed instructions as to recording of symptoms, identification of catheter displacement, and hardware failure should be given to the patient. It is the recommendation that such verbal instructions should be reinforced by written instructions, and, in addition to the hardware built into the system, the patient is provided with a simple diary to record events. This allows correlation of the test observations with symptoms.

Analysis

Quality Assessment

The first step in the analysis of an ambulatory UDS trace is the assessment of the quality of data recorded. The specific points that should be addressed with regard to pressure measurement are as follows:

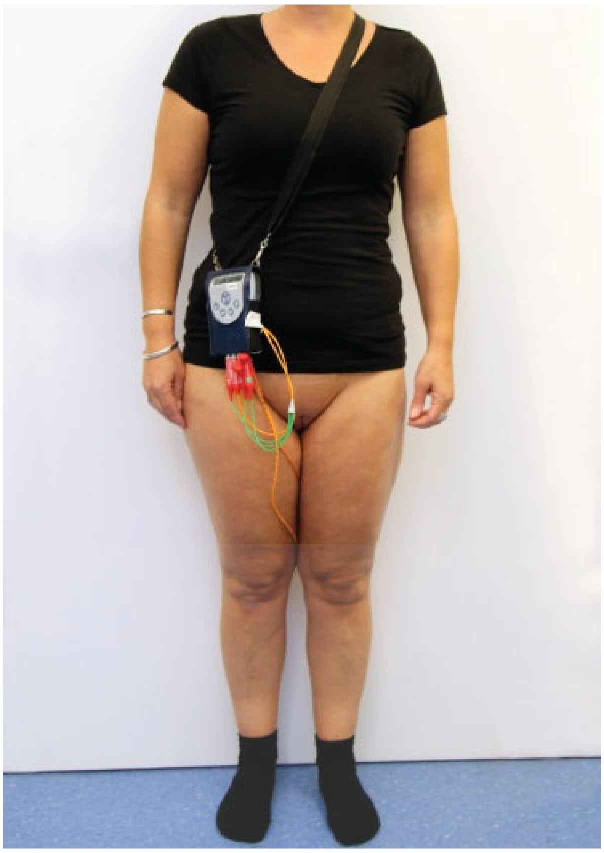

Figure 35.4 Overview on how the catheters are connected to the portable recording unit during a four to seven hour measurement.

- Is the trace "active," i.e., fine second-to-second variation in pressure is visible (indicating breathing and body movement), rather than a completely flat line?
- Is the baseline static or highly variable?
- Are the cough tests or other activities causing abdominal pressure changes that can be used for signal plausibility check regularly present?
- Is the subtraction adequate, e.g., minimal change in subtracted detrusor pressure with coughing?

If the technical quality of the traces is less than perfect, then, although the investigation may yield valuable clinical information, the information that can still be derived from the traces is very much dependent on the experience of the team and the person responsible for the interpretation of the assessment.

Phase Identification

Depending on the purpose of the investigation, markers must be placed to identify voluntary voids and allow differentiation of such events from involuntary events, which may be associated with changes in recorded pressure. The protocol of the investigation should state specifically the point at which the markers identifying commencement and cessation of a voluntary void are placed. Analysis of the voiding phase follows the same principles and terminology used during conventional pressure–flow investigation.

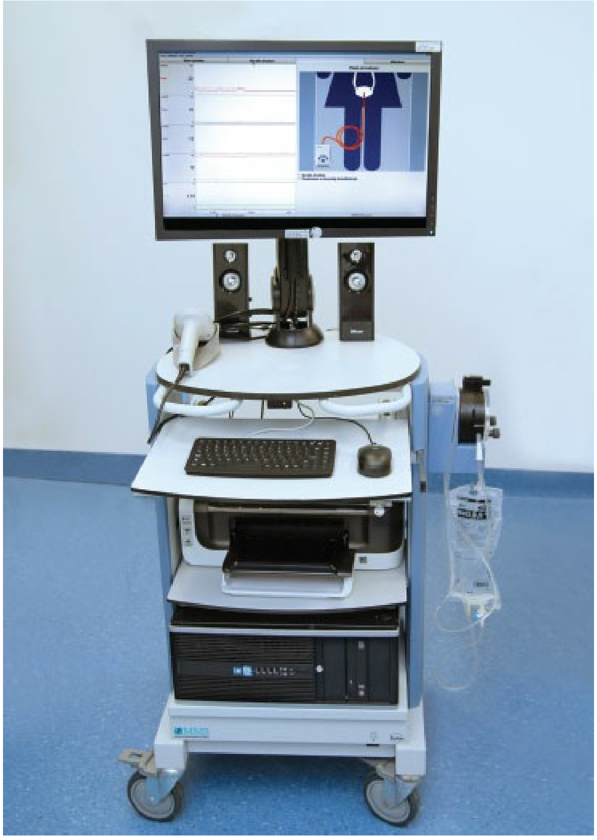

Figure 35.5 General urodynamic filling, recording, and monitoring system. The system is used to check catheter position before fixation and connection to the portable unit. In addition, data from the portable recording unit are transferred to this system after the ambulatory measurement has ended.

Events

The use of a patient diary considerably improves the detailed analysis of events occurring during ambulatory UDS and is a necessity for adequate interpretation. In addition, it has proven very valuable as a double check for both patient and equipment compliance. Typical events occurring during the filing phase are detrusor contractions, urethral relaxation, and episodes of urgency and incontinence.

CLINICAL REPORT

The report should be tailored to the urodynamic indication(s) and can include the following:

- Whether symptomatic complaints were reproduced during the test
- Duration of recording
- Filling rate, timing, method, and volume of any retrograde filling before commencing ambulatory UDS
- Dose and timing of diuretics, if administered
- Volume of fluid intake during the assessment
- Number of voids
- Total and range of voided volumes and postmicturition urinary residual
- Episodes of urgency, urinary incontinence, and pain
- Detrusor activity during the filling phase (frequency, time, duration, amplitude, area, form)
- Pressure–flow analysis
- Results of provocative maneuvers employed during the test
- In case of premature termination, reason for termination of recording

COMMENTS

Additional to the ICS standardization report, there are several recommendations to ensure quality control during ambulatory urodynamics, as follows.

Patient Preparation

- The patient should be instructed before the assessment on the following:
  - Reasons of execution of ambulatory UDS.
  - Duration of the assessment (in general between 4 and 7 hours) [2].
  - How to fill out the diary, in detail (Figure 35.2). This will provide information on activity during the assessment, which is essential for optimal performance of the ambulatory UDS.
  - Behavior during the assessment (this should be as in the normal, daily situation).
  - Wearing loose comfortable separate clothing.
- Catheters are inserted using an aseptic technique. Catheters are placed in the bladder, urethra, and rectum and brought into optimal position.
- After insertion, the catheters are taped to the inner thigh (sometimes also to the pubic region for optimal fixation), close to the labia (as close to the urethra as possible) using several pieces of 5 cm medical tape. After fixation, catheter positions should be checked again and, in case necessary, corrected for optimization of the pressure–flow traces.

Procedure

- The patient should use the timer on the ambulatory box, not her own watch.
- The patient is instructed how to use the event button. In the event of a toilet visit, the button is pressed when entering the bathroom or at the starting point of voiding and pressed again once voiding has finished. When fluids are consumed, or during an episode of urgency, the relevant buttons are used. Instructions for the use of the event buttons should be included on the diary sheet, as should the instructions on how to fill out the diary.
- In case of problems or discomfort, the patient should be able to contact the coordinator easily. This is also important for the quality of the assessment.
- At the end of the assessment, the patient should be asked to perform a series of activities, such as coughs, which can improve diagnostic yield. After this, the patient is asked to void.
- After completion, the patient’s diary is checked and, if necessary, discussed with the patient present. The traces and diary can be interpreted with the patient still present or at a later stage. If the traces are interpreted in a later stage, the diary must have been filled out correctly by the patient and event markings been recorded correctly. This is important for linking symptoms to the ambulatory urodynamic outcome.
- After the test, the patient is warned that she may have an irritative feeling in the urethra and bladder for up to 24 hours and is advised to maintain optimal fluid intake. If symptoms suggesting cystitis are persistent or urine becomes offensive, the patient should seek advice from her doctor. Anders et al. [25] showed that there is no indication for antibiotic prophylaxis for patients who undergo an ambulatory UDS and had no positive urine culture prior to the assessment. However, in case of known residuals, vesicoureteric reflux or recurrent urinary tract infections (UTIs), antibiotic prophylaxis should be given.

CLINICAL APPLICATION

Patient Bother

In general, conventional UDS is well tolerated in women [26]. Compared to conventional urodynamics, ambulatory UDS has a longer duration (4–7 hours), making it more prone to bother. However, two studies of Oh et al. in 40 patients (33 women and 7 men) showed that conventional UDS appeared to have a higher degree of anxiety than ambulatory UDS ($p = 0.045$), while boredom was significantly more during ambulatory UDS ($p = 0.013$), with no significant difference in embarrassment or bother between both assessments [27]. In addition, the degree of intolerance decreased significantly at second ($p = 0.016$) and third ($p = 0.049$) ambulatory urodynamic assessments [28].

Ambulatory UDS and Storage Dysfunction

Poor Correlation between Symptoms and Conventional UDS

Several studies already showed that urinary symptom diagnosis and conventional urodynamic diagnosis differ [29–31]. A study in 209 nonneurogenic patients (92 women and 117 men) with persistent OAB symptoms showed detrusor overactivity (DO) on conventional urodynamics in only 58.7% [32]. Haylen et al. [33] showed that none of the OAB symptoms alone can accurately predict DO on conventional urodynamics. Sekido et al. [34] retrospectively evaluated 50 patients (38 women and 12 men) with OAB symptoms in relation to the presence or absence of DO. The overall incidence of DO was 36.8% in the female patient group, making the bladder an unreliable witness for predicting detrusor overactivity on conventional UDS [35].

Ambulatory UDS versus Conventional UDS in Storage Dysfunction

Although ambulatory UDS is a relatively elaborate and time-consuming investigative tool to perform and to analyze, it is thought to be a more accurate tool for diagnosing LUT dysfunctions in both children and adults [23,36]. In case of DO, ambulatory UDS has been reported to have a higher sensitivity compared to conventional UDS [8,11]. Patravali et al. showed that ambulatory UDS can diagnose urinary dysfunction in 77% of symptomatic women with inconclusive conventional urodynamics. These results are in line with earlier results from Anders et al. in 475 symptomatic women [37]. Radley et al. [13] compared ambulatory UDS and conventional videocystometry findings in 106 women with OAB symptoms. They showed a significant difference ($p < 0.001$) in the detection of DO, with a higher prevalence detected using ambulatory UDS. No significant difference was seen when comparing stress incontinence rates in both groups ($p = 0.629$).

The difference in observations between both assessment types could be explained by the technique used. The retrograde, rapid bladder filling and the shorter time span of conventional urodynamics may very well lead to an underestimation of DO. However, it cannot be excluded that the vesical catheter itself is a nonphysiological trigger resulting in a higher incidence of detrusor overactivity during ambulatory urodynamics [38]. In addition, a previous study in healthy female volunteers showed DO on ambulatory UDS in 68% of the cases, compared to 18% after conventional UDS [39]. Salvatore et al. [40] showed that the symptom diary and potentially also the placement of two transducers in the bladder can decrease the finding of pathological detrusor activity on ambulatory UDS by minimizing possible artifacts.

There still remains a lot of controversy regarding the clinical implications of using urodynamics in OAB patients [41]. Giarenis et al. [42] recently showed that women with OAB and additional DO on conventional or ambulatory UDS experience a more significant impairment to their quality of life and have a greater degree of bladder dysfunction compared to OAB patients without DO on urodynamics.

In clinical practice, ambulatory urodynamics can be of additional value in the specific group of treatment of refractory OAB patients without DO on conventional UDS. The fact that the bladder produces involuntary detrusor contractions in response to the small flexible catheters during an ambulatory urodynamic measurement itself might indicate a higher excitability of the bladder sensory function or a decreased central inhibition of the urethra–detrusor facilitative reflex contractions in the filling phase [43]. This might even serve as a biomarker of pathology. To accomplish this, quantification and characterization of DO on ambulatory UDS is necessary. In the past, van Waalwijk van Doorn and Ambergen [44] started with characterization of DO by development of the detrusor activity index. However, this method is used seldom in clinical practice.

Ambulatory UDS and Incontinence

In case of urinary incontinence with uncertainty about the underlying cause, conventional urodynamics in general does not give sufficient additional information on the pathophysiological background. The advantages of ambulatory UDS having a longer recording period, multiple micturition cycles, additional stress testing, and the observation of urinary leakage combined with pressure–flow traces make it more suitable for potential detection of the predominant cause of the urinary incontinence (Figure 35.6).

Robinson et al. [45] assessed whether ultrasound bladder wall thickness measurement could replace ambulatory urodynamics in 128 patients women with a conventional urodynamic diagnosis not explaining their urinary symptoms. The authors concluded that in women with stress incontinence ambulatory urodynamics remains the investigation of choice.

There is currently only limited literature on the specific role of ambulatory UDS in the identification of the origin of incontinence with attention to DO as well as the stress component. However, the available literature suggests that ambulatory UDS improves the ability to detect an underlying pathophysiology compared to conventional urodynamics [15].

Pharmacological Treatment Monitoring

Ambulatory urodynamics can be used for the evaluation of pharmacological OAB treatment and potentially has advantages over conventional UDS based on the design of the ambulatory assessment. The optimal duration to yield useful information appears to be 6 hours [46] (Figure 35.7). A study by Chapple and Abrams comparing darifenacin and oxybutynin in patients with OAB showed that ambulatory UDS can potentially be a useful investigative tool in the evaluation of therapeutic agents [47].

The topic of ambulatory UDS pharmacological treatment evaluation is still heavily under discussion [48] as Oh et al. published a study suggesting that ambulatory UDS does not take into account the patient perception of bladder condition after treatment [49]. In addition, correlations between the patient view of treatment outcome and urodynamic measures are poor [49]. However, most studies have a small sample size, emphasizing the need for larger studies to evaluate the usefulness of ambulatory UDS to this respect.

Effective Evaluation of Invasive OAB Treatment: Sacral Neuromodulation and OnabotulinumtoxinA

There is currently only one study presenting results on treatment evaluation using ambulatory UDS as a diagnostic outcome tool. Scheepens et al. [50] published a study in OAB patients treated with sacral neuromodulation (SNM) and described a correlation between reduction in involuntary detrusor contractions and clinical outcome after treatment. This, together with clinical experience, shows that ambulatory urodynamics is potentially a useful diagnostic tool in the evaluation of SNM treatment.

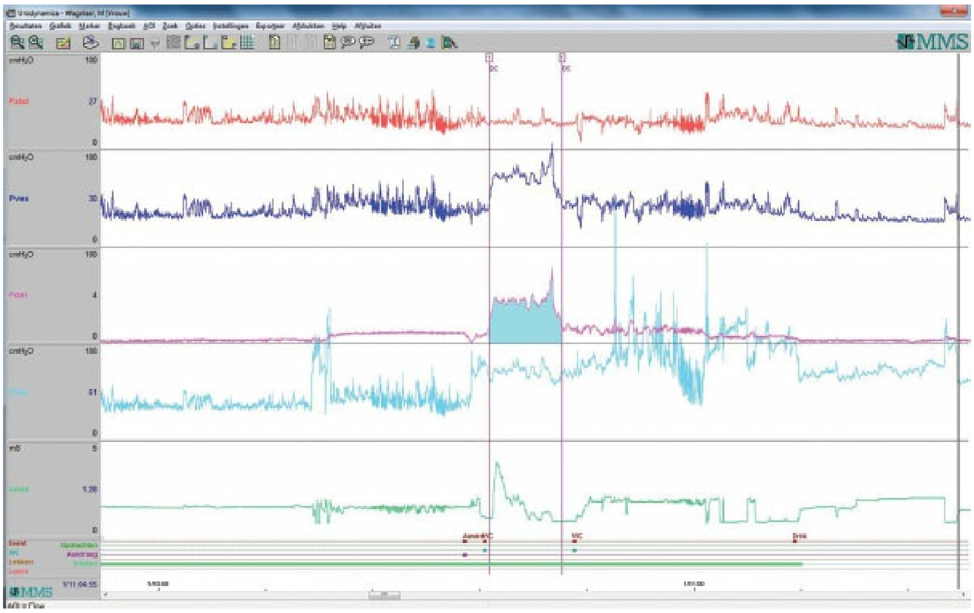

Figure 35.6 Ambulatory urodynamic trace showing bladder contractility in a patient after sacral neuromodulation (SNM) test phase. This specific patient had bladder acontractility before SNM testing. Additionally, there is a lack of urethral relaxation. “DC” marker: detrusor contraction, indicating the start and end of a detrusor contraction (detrusor overactivity if during the filling phase). “Aandrang” marker: represents the urgency event. “WC” marker: indicating start and end of the toilet visit.

In contrast, there are no data available on ambulatory urodynamic evaluation of onabotulinumtoxinA treatment. However, a study analyzing conventional UDS showed that results after intradetrusor injections of onabotulinumtoxinA in idiopathic OAB patients were not predicted by the presence of detrusor overactivity on pretreatment conventional UDS [51].

Ambulatory UDS and Spinal Cord Injury Patients

Spinal cord injury (SCI) patients routinely have a urodynamic follow-up to detect poor compliance, high-pressure storage, or neurogenic DO, which can lead to incontinence, bladder stones, UTIs, or upper urinary tract deterioration. In the context of SCI patients, there have been new ambulatory system developments recently. In 28 patients, a new system, with abdominal pressure measurement using surface EMG patches, was tested [52]. These patches appeared to be able to replace the use of a rectal catheter.

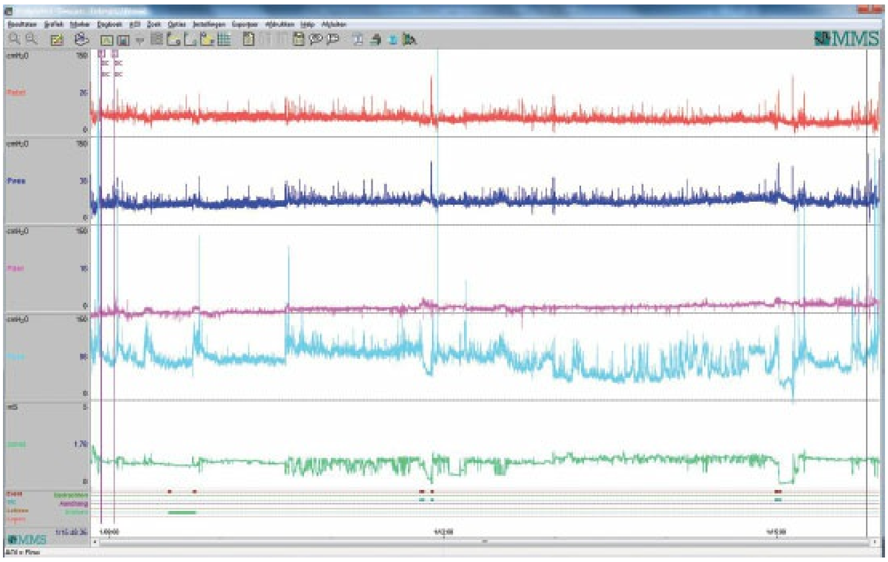

Figure 35.7 Ambulatory urodynamic trace overview in a 6 hour measurement.

Despite these developments and the reliability for reproducible results [36], a recent study of Martens et al. concluded there is no primary role for ambulatory urodynamics in SCI patients [17]. All included patients underwent conventional and ambulatory UDS, resulting in a larger number of patients diagnosed with DO after ambulatory UDS. However, there was no significant difference in bladder pressure measured during DO. According to the authors, the higher DO rate on ambulatory UDS was based on artifacts. Although conventional UDS might underdiagnose NDO, a good clinical assessment combined with video urodynamics is sufficient in making an accurate diagnosis of NDO in SCI patients [17,53].

AMBULATORY UDS AND VOIDING DYSFUNCTION

Voiding dysfunction can have different causes related to the bladder outlet or intrinsic bladder characteristics. Causality can vary from bladder outlet obstruction (in women, e.g., strictures or previous surgery) or dysfunctional voiding to detrusor underactivity or an acontractile bladder.

Detrusor underactivity is defined by the ICS as a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span [24]. Bladder acontractility is characterized by an inability to empty the bladder completely, without a visible contraction on cystometry. Clinically, these patients present with the inability to void to completion and/or with recurrent UTIs or urinary retention. Both detrusor underactivity and bladder acontractility can be caused by dysfunction at various levels in the CNS–bladder axis, from damage to the detrusor muscle or its autonomic nerve supply to dysfunction at spinal or brain level [54].

Bladder acontractility represents a heterogeneous urological entity, and the etiological variety forces us to search for different therapeutic approaches. A first step in this process is finding the most optimal diagnostic tool in diagnosing true bladder acontractility. Currently, there is only limited evidence relating ambulatory urodynamics and bladder acontractility. Van Koeveringe et al. [2] pointed out the value of ambulatory UDS in differentiating LUTS etiology. In a subgroup of 25 patients, suspected of having acontractility based on conventional UDS, bladder acontractility was confirmed in only 16% of the cases after ambulatory UDS. All other patients (21 out of 25) still had contractions present on during ambulatory UDS and therefore were not diagnosed with bladder acontractility [2]. This initial pilot study highlighted the potential of ambulatory UDS in diagnosing detrusor underactivity and bladder acontractility (Figure 35.8).

Current treatment options for restoring voiding effectiveness in patients with complete ambulatory UDS–confirmed bladder acontractility are limited. Bladder and sphincter reflex modulation techniques such as SNM can only be used if there is little or no damage to the CNS–bladder axis, in combination with intact function of the detrusor contractile apparatus. Therefore, in the right selection of patients (with at least some contractile function present on ambulatory UDS), this therapeutic option can be effective [55,56]. Moreover, a reconstructive surgical procedure such as latissimus dorsi detrusor myoplasty is only feasible in a highly selected group of patients with an acontractile bladder [57,58]. This means that the majority of patients are left with no other options than performing lifelong CISC [59].

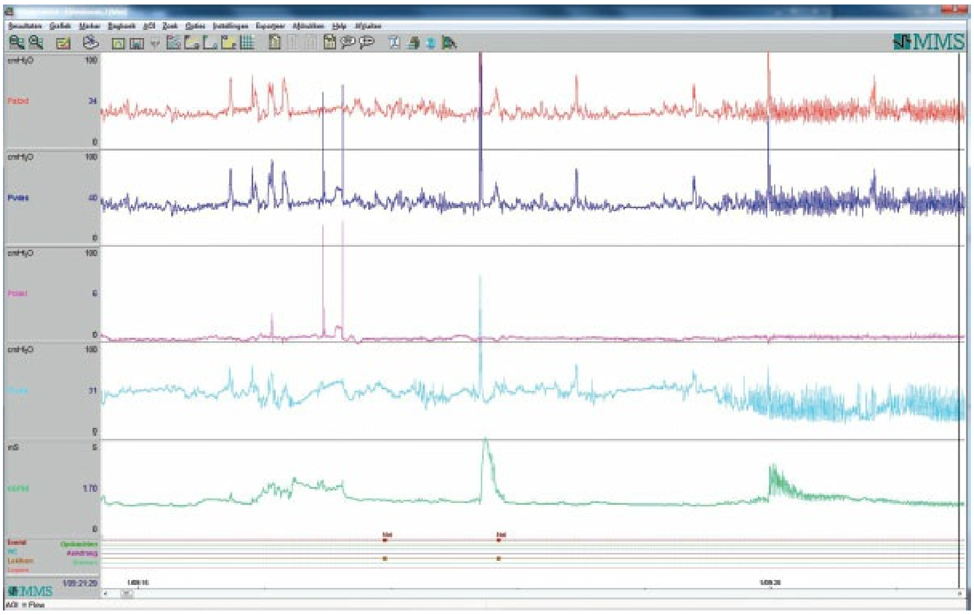

Figure 35.8 Ambulatory urodynamic trace indicating stress urinary incontinence by simultaneously steep peaking of the abdominal and vesical pressure with coinciding raised conductance and marker use. “DC” marker: detrusor contraction, indicating the start and end of a detrusor contraction (detrusor overactivity if during the filling phase). “Aandrang” marker: represents the urgency event. “WC” marker: indicating start and end of the toilet visit. “Nat” marker: indicating urinary loss objectified by the patient.

In order to increase the success rate of the invasive, limited, and more expensive therapeutic options such as sacral neuromodulation, there is a need for a valid diagnostic tool in patients with suspected bladder acontractility. Hence, ambulatory UDS is expected to gain a more prominent role in the diagnostic algorithm for detrusor underactivity and the differentiation of this entity from true bladder acontractility [60].

CONCLUSIONS

Ambulatory urodynamic monitoring is a valuable discriminating diagnostic tool in patients with various LUT complaints, particularly when conventional urodynamics fail to explain the symptoms. Ongoing research focuses on extending the application possibilities, particularly increasing attention to the role of ambulatory urodynamics in the assessment of bladder contractility or mixed urinary incontinence.

ACKNOWLEDGMENTS

Portions of this chapter were derived from Chapter 35, in the Textbook of Female Urology and Urogynaecology, third edition. We express our gratitude to Stefano Salvatore, Vikram Khullar, and Linda Cardozo for their work with respect to the particular parts of this chapter.

36 Basic Neurological Evaluation and Referral

David B. Vodušek and Jalesh N. Panicker

INTRODUCTION

Recordings of bioelectrical activity from muscles and the nervous system have been found clinically useful and named “clinical neurophysiology tests.” (Sometimes, tests other than electrophysiological investigations of nervous functions are listed as “neurophysiology,” but these other tests will not be described in this chapter.)

Clinical neurophysiology tests are many and are grouped together into subcategories according to different criteria. It is practical to distinguish recordings from muscle (electromyography) and tests of nerve and nervous pathway function (conduction studies). Typically, the different tests are referred to with disconcerting capital letter abbreviations, and even professionals close to the field have some difficulty in understanding the terminology and complex physiological and technical background of the methods, and distinguishing the different types of information provided by different tests. This chapter aims at clarifying these issues.

Recording Electrical Muscle Activity: Electromyography

Electromyography (EMG) is the extracellular recording of bioelectrical activity generated by muscle fibers. Modern EMG started with the introduction of the concentric needle electrode (CNE) in 1929 [1], the design of which has endured ever since, almost unchanged (Figure 36.1) [2]. Clinical EMG studies of the pelvic floor were sparse till the 1970s; since then, EMG has been used increasingly in urogynecology, neurourology, and proctology research. Nowadays, it is used as a routine diagnostic investigation.

EMG may be performed for two quite distinct, although complementary, purposes. On the one hand, it can reveal the “behavior” (i.e., patterns of activity) of a particular muscle; on the other hand, it can be used to demonstrate whether a muscle is normal, myopathic, or denervated/reinnervated. The former can be called “kinesiological EMG” and the latter “motor unit” EMG, but usually, this division is not specified and both types of examination are just called “EMG,” which can confuse the uninitiated. There are, of course, anatomical, physiological, and practical specificities of pelvic floor and perineal EMG, but the techniques are intrinsically the same for all striated muscles.

Testing Conduction across Nerves and Nervous Pathways

Conduction studies examine the capacity of a nerve (or nervous pathway) to transmit a test volley of depolarization elicited by a stimulus along its length. Tests have been as a rule introduced for limb nerves (and their central connections) and only later modified by workers in pelvic (uro-) neurophysiology [2].

Conduction along a nerve (or central nervous system pathway) depends on the anatomical integrity of the structure. In finer detail, the velocity of conduction depends on the thickness of constituent axons and their myelin sheath. All these may be altered by pathology and reflected as changes in either the latency of the recorded response (or velocity of conduction) or the amplitude (and configuration). It needs to be appreciated that “pure” conduction via nervous pathways is only measured where there is no synapse between the stimulated and the recorded sites (such as in stimulating a nerve and recording from the same nerve). The “conduction” across several synapses (as in recording a reflex response) is not only “longer” because of synapses but also variable (dependent on various additional factors, not only anatomical integrity and myelination).

Testing a nerve with a motor function, its responsiveness can be measured by the electrical stimulation of the nerve and recording the elicited muscle response (Figure 36.2). Both the time taken to muscle activation (latency) and the amplitude of the muscle response (known as the compound muscle action potential or “M” response) can be measured [2]. The latter depends on the number of intact individual motor fibers, whereas measures of motor latency (i.e., time to onset of response) and motor conduction velocity (CV) reflect the conduction speed of the fastest nerve fibers. For this reason, measures of latency are a poor guide to the integrity of innervation. The amplitude of the evoked muscle response gives a better guide, but because this measurement depends so heavily on the configuration of the electrodes employed, amplitude is not as valuable as might have been expected on a theoretical basis. Ideally, to measure compound muscle action potential amplitude, the reference electrode should be placed over the tendon and the active recording reference over the motor end plate (i.e., point of entry of nerve into muscle). For a strap-shaped muscle, this can be identified as midway along its anatomic length, but in more anatomically complex muscles such as those in the pelvis, the motor end plate region has not been identified and recording well-formed compound muscle action potentials is difficult.

The nerve roots carrying nerve fibers for particular muscles can be stimulated over the spinal column, thus testing the conduction over the whole length of the peripheral motor axons. The stimulation of the motor cortex area for particular muscle groups can be achieved from the scalp, thus testing the whole motor pathway (both central and peripheral). The muscle responses obtained by such stimulation are called motor evoked potentials (MEPs).

If the peripheral nerve being tested is accessible over sufficient length, so that stimulating and recording electrodes can be placed at some distance from each other (at least 10 cm is recommended to lessen stimulus artifact), it may be possible to record nerve activity directly. This response is called a “compound nerve action potential.” The amplitude of a compound nerve action potential is related to the number of nerve fibers being depolarized by the stimulating impulse and is a good measure of the number of active nerve fibers.

Needle recording electrode	Needle tip and recording surface	Pick-up	Needle diameter	Filter settings	Activity recorded
Concentric needle electrode: central insulated platinum wire inside a steel cannula		Hemisphere radius 0.5 mm	0.3–0.65 mm	5–10 kHz	Motor units
Single-fiber needle electrode: fine platinum wire (25 μm diameter) inside steel cannula which records from a side aperture		Hemisphere radius 250–300 μm	0.5–0.6 mm	500–10 kHz	Individual muscle fibers of motor units. In health the potentials are either singles or pairs: after reinnervation the potentials have multiple components

Figure 36.1 The concentric needle electrode and the single-fiber needle electrode, their physical characteristics, the filter settings required for use, and the nature of the activity that each records. (Modified from *Clinical Neurophysiology: EMG, Nerve Conduction and Evoked Potentials*, Vol. 1 (revised and enlarged edition), Fowler C and Tedman B, Electromyography: Normal and pathological findings. Copyright 2004, with permission from Elsevier.)

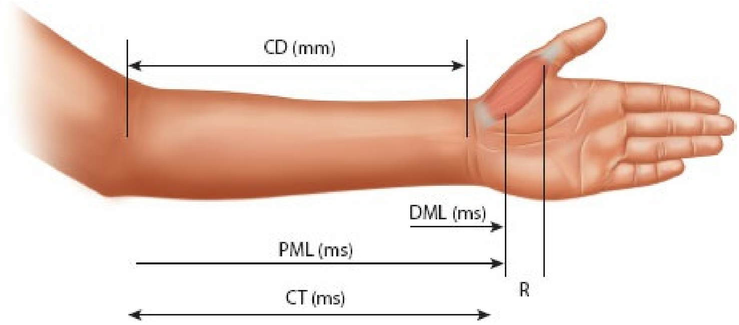

Figure 36.2 Measurements to be made in calculating motor conduction velocity (CV). (CD, conduction distance; CT, conduction time; DML, distal motor latency; PML, proximal motor latency; R, recording

electrodes. CV = CD/CT.)

If the stimulated nerve is purely sensory, as may be the case for some peripheral cutaneous branches, the compound nerve action potential is called the sensory neurogram (sensory nerve action potential). Such recordings are not routinely practical in the pelvis for anatomic reasons.

On stimulation of sensory nerves or the innervated skin or mucosa, an "electrical" response from the central nervous system (i.e., from the spinal cord and the brain) can be recorded. The recorded potentials are called somatosensory evoked potentials (SEPs).

On stimulation of sensory receptors in the skin or mucosa, or stimulation of sensory nerves, reflex responses are also elicited and can be recorded (for instance, the bulbocavernosus reflex). The commonly adopted technique is to apply a series of single electrical stimuli via surface electrodes to the dorsal clitoral nerve (above the clitoris) and record the consecutive reflex responses from the anal sphincter with a concentric needle EMG electrode.

Motor Unit

Knowledge of the structure and function of the motor unit is fundamental to understanding the application of EMG methods.

"Muscle electrical activity" is generated by depolarization of single muscle fibers (i.e., consisting of muscle fiber action potentials). But the innervation of muscle is such that a single muscle fiber does not contract on its own, but rather in concert with other muscle fibers that are part of the same motor unit, i.e., innervated by the same motor neuron.

Motor neurons that innervate striated muscle lie in the anterior horn of the spinal cord. Their cell bodies are relatively large and their axonal processes correspondingly of large diameter and myelinated to allow rapid conduction of impulses, although the neurons that innervate the sphincters are relatively smaller than those innervating the skeletal limb and trunk muscles. Within the muscle, the motor axon tapers and then branches to innervate muscle fibers that are scattered throughout the muscle (Figure 36.3). The innervation of muscle is such that it is unlikely that fibers that are part of the same motor unit will be adjacent to one another. The number of muscle fibers innervated by an axon is known as the "innervation ratio." There is no simple neurophysiological method for estimating this parameter, and the number of motor units per muscle is also difficult to estimate by clinical neurophysiological means.

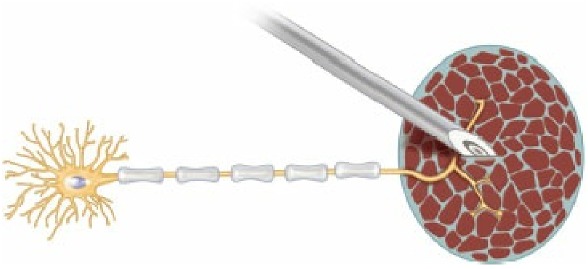

Figure 36.3 Diagram of a motor unit showing the motor neuron that is located in the anterior horn of the spinal cord, Onuf's nucleus in the case of the sphincters, and the motor axon that travels in the peripheral nerve to the muscle. Here, it divides, innervating a number of muscle fibers, most of which are not adjacent. (Modified from *Clinical Neurophysiology: EMG, Nerve Conduction and Evoked Potentials*, Vol. 1 (revised and enlarged edition), Fowler C and Tedman B, Electromyography: Normal and pathological findings. Copyright 2004, with permission from Elsevier.)

The contraction properties of a motor unit depend on the nature of its constituent muscle fibers. Muscle fibers can be classified according to their twitch tension, speed of contraction, and histochemical staining properties. The fatigue-resistant type 1 fibers constitute motor units that fire for prolonged periods of time at lower firing frequencies, i.e., "tonically" (see in the succeeding text). Type 2 fibers make up motor units that fire briefly and rapidly in bursts, i.e., "phasically." Unfortunately, there is no clinical electrophysiological method that can estimate the proportion of motor units of different muscle fiber types. In the pelvic floor and sphincters, the majority of muscle fibers are type 1 (with some regional variation).

ELECTROMYOGRAPHIC METHODS

Kinesiological EMG

Method

By prolonged recording of bioelectrical activity of a muscle, a qualitative and quantitative description of its activity over time is obtained. Such techniques are used in rehabilitation and sports medicine to study movement. Meaningful kinesiological EMG can, of course, only be performed from an innervated muscle. If the lower motor neuron integrity of a particular muscle is questioned, "motor unit" EMG analysis (see succeeding text) has to be performed first.

The choice of muscle for EMG examination depends on the aims of the investigation. Routine EMG as part of urodynamic testing usually employs a single channel for recording from the urethral or anal sphincter muscle. The sphincters being small circular muscles, it is assumed that the two sides react in a similar fashion, although this may not always be the case, as was shown for the levator ani [3].

When we are interested in the pattern of activity of an individual muscle, the technique should ideally provide a selective recording, uncontaminated by neighboring muscles on one hand and a faithful detection of any activity within the source muscle on the other hand. Unfortunately, both objectives are difficult to achieve simultaneously and the purpose of the investigation will suggest an acceptable compromise. Overall detection from the bulk of a muscle can only be achieved with nonselective electrodes; selective recordings from small muscles can only be made with intramuscular electrodes with small detection surfaces. Nonselective recordings carry the risk of contamination with activity from other muscles; selective recordings may fail to detect activity in all parts of the source muscle. Meaningful recordings from deep muscles can only be accomplished by invasive techniques.

Considering the aforementioned, truly selective recording from sphincter muscles can probably only be obtained by intramuscular electrodes; in clinical routine, often, the CNE is used. This electrode has the advantage of being widely available, easy to introduce, and adjustable in position and has a standardized active surface. It is, however, painful to have inserted and subsequent movement of the source muscle can be uncomfortable and the needle then easily dislodged. Instead, two thin isolated/bare tip wires (with a hook at the end) can be introduced into the muscle with a cannula; the latter is then withdrawn, and the wires stay in place. The advantage of this type of recording is good positional stability and painlessness once the wires are inserted, although their position cannot be much adjusted.

To make EMG recording less invasive, various types of surface electrode have been devised; also, there are alternatives for intravaginal placement [4], anal plug electrodes, and catheter-mounted ring electrodes [5] to record from the urethral sphincter (Figure 36.4).

Recordings with surface electrodes are more artifact prone and, furthermore, the artifacts may be less easily identified. Critical online assessment of the "quality of the EMG signal" is mandatory in kinesiological EMG, and this requires either auditory or oscilloscope monitoring of the raw signal. Integration of high-quality EMG signals may help in quantification of results, as can automatic analysis of the interference pattern [6].

Findings in Normal and Abnormal Conditions

The normal kinesiological sphincter EMG shows some continuous activity at rest (which may be increased voluntarily or reflexly) (Figure 36.5); such activity could be recorded for up to 2 hours and even after a subject has fallen asleep during the examination [7]. This physiological spontaneous activity may be called "tonic." It consists of prolonged firing of tonic motor units, not rapidly interchanging activation and inactivation of different motor units [7].

The "amount" of recorded activity depends on the uptake area of the electrode (Figure 36.1). Using a CNE, activity from 1 to 5 motor units is usually recorded per detection site in the anal sphincter at rest. "Tonic" activity is encountered in many but not all detection sites of the levator ani muscle [8]. Typically, it consists of low-amplitude motor unit potentials (MUPs) that fire fairly regularly at low frequencies. In a study of 39 such motor units from the anal sphincter in 17 subjects (inclusion criterion was rhythmic spontaneous firing for 2 minutes before onset of measurement), the range of discharge rates was found to be 2.5–9.4 Hz. Any reflex or voluntary activation procedure is mirrored first by an increase in the firing frequency of the motor units; then, with any stronger activation or increase in abdominal pressure, the new so-called phasic motor units are recruited (Figure 36.5). These are usually of higher amplitude and their discharge rates are higher and irregular. A small percentage of motor units with an “intermediate” activation pattern can also be encountered. Both the urethral and anal sphincters show short-lasting voluntary activation times (typically below 1 minute), which is also the case for pubococcygeus muscles [8].

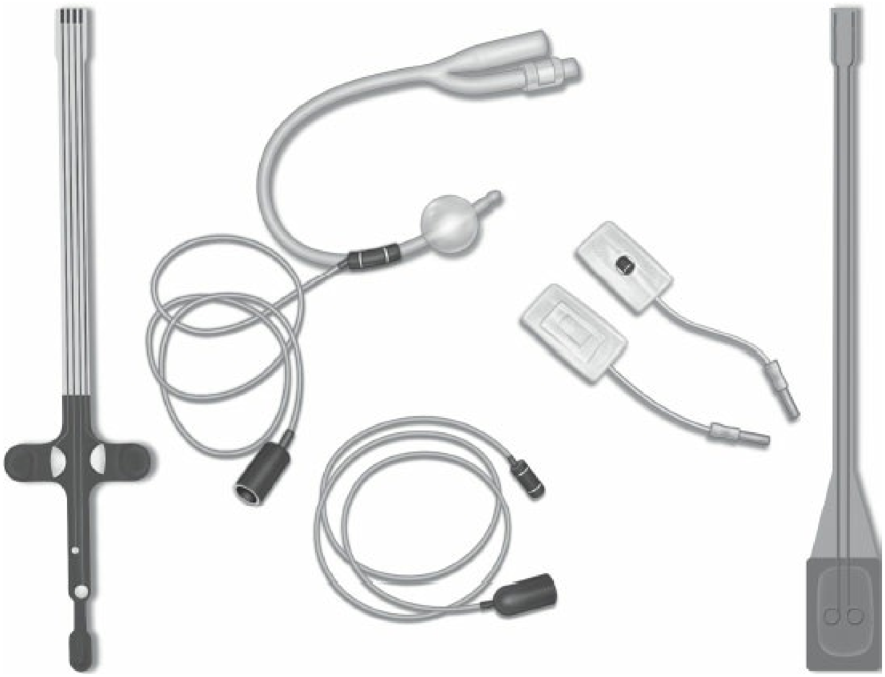

Figure 36.4 Electrodes used to record sphincter activity. (Reproduced from *Clinical Neurophysiology: EMG, Nerve Conduction and Evoked Potentials*, Vol. 1 (revised and enlarged edition), Fowler C and Tedman B, Electromyography: Normal and pathological findings. Copyright 2004, with permission from Elsevier.)

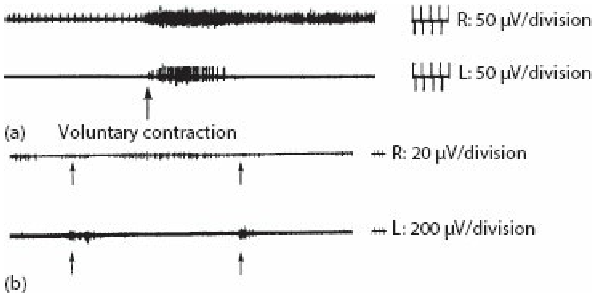

Figure 36.5 Kinesiological EMG recordings from the pubococcygeus muscles (recording with intramuscular wires: right, upper traces; left, lower traces). (a) Recordings from a 33-year-old nulliparous woman. Continuous firing of motor unit potentials is seen on the right with a gradual recruitment on voluntary contraction. On the left, no ongoing activity is present. Symmetrical recruitment on voluntary contraction is present. (b) Recordings from a 52-year-old stress urinary incontinent woman. Some ongoing muscle activity can be seen in both pubococcygeal muscles. On voluntary contraction, recruitment can only be seen on the left. On the right, there is actually a decrease in firing of motor units on “voluntary contraction.”

On voiding, all EMG activity in the urethral sphincter ceases prior to a detrusor contraction. Coordinated detrusor/sphincter activity is lost with lesions between the lower sacral segments and the upper pons (the pontine micturition center); detrusor contractions are then accompanied by an increase in sphincter EMG activity [9]. This pattern of activity is called “detrusor sphincter dyssynergia.” On the basis of the temporal relationship between urethral sphincter and detrusor contractions, three types of dyssynergia have been described [10]. This neurogenic uncoordinated sphincter behavior has to be differentiated from “voluntary” contractions that may occur in the so-called nonneuropathic voiding disorders that may be a learned abnormality of behavior [15] and may be encountered in women with dysfunctional voiding [11].

Failure of relaxation of urethral sphincter contraction during detrusor contractions has also been reported in patients with Parkinson's disease [12]. The normal physiological behavior of the striated anal sphincter is characterized by its relaxation with defecation [13]; a paradoxical sphincter activation during defecation has been described in Parkinson's disease, the so-called anismus [1].

The pubococcygeus in the healthy female reveals patterns of activity similar to those found in the urethral and anal sphincters at most detection sites, i.e., continuous activity at rest, some increase in activity during bladder filling, and a reflex increase in activity during any activation maneuver such as talking, deep breathing, and coughing. It relaxes during voiding, and in health, the muscles on both sides act in concert [8]. Timely activation of the levator ani muscle has been demonstrated to be an important aspect of stable bladder neck support; its activation precedes activity of other muscles in the cough reflex [14]. In stress-incontinent women, the physiological patterns of activation, as well as the coordination between the two sides, may be lost [3] (Figure 36.5). A delay in muscle activation on coughing has also been demonstrated, as compared to continent women [15].

Little is known about the normal complexity of activity patterns of different pelvic floor muscles (i.e., urethral sphincter, urethrovaginal sphincter, anal sphincter muscle, different parts of the levator ani), but it is generally assumed that they act as one, in a coordinated fashion. Differences have, however, been demonstrated even between the intra- and periurethral sphincter [16]. Coordinated behavior is often lost in disease states, as has been shown, for example, for the levator ani and the urethral and anal sphincters [17]. Disturbances of pelvic floor muscles activity have been modified by using the kinesiological EMG recording as a biofeedback signal [18].

Diagnostic Usefulness of Kinesiological EMG

The demonstration of voluntary and reflex activation of pelvic floor muscles is indirect proof of the integrity of respective neural pathways. Kinesiological EMG recordings of sphincter muscles, either urethral or anal, are obtained in selected patients in urodynamic laboratories to ascertain sphincter behavior during bladder filling and voiding. Such simultaneous studies of detrusor and sphincter activity are, as a rule, obtained only in patients with suspected detrusor–sphincter dyssynergia. External anal sphincter EMG is recorded in some laboratories in the assessment of anorectal dysfunction [13].

Other than the polygraphic urodynamic recordings to diagnose detrusor–sphincter dyssynergia, the diagnostic contribution of kinesiological EMG is yet to be established and is now rarely recorded for several reasons. It is often technically difficult to obtain a good quality EMG signal from a site that is as inaccessible as the urethral sphincter. The best signal is obtained using a needle electrode, but the discomfort from the needle itself is likely to impair normal relaxation of pelvic floor muscles including the urethral sphincter. The alternative of surface recording electrodes has been used, but they record activity from other muscles as well, which makes interpretation of the results difficult. With the advent of video-urodynamics, which permits multichannel cystometry and pressure/flow studies of voiding with synchronous fluoroscopic screening, much of this information about the outflow tract is obtained from a less-invasive investigation.

EMG Methods to Differentiate Normal from Pathological Muscle

Needle EMG may help to differentiate between normal, denervated, reinnervated, and myopathic muscle. Such EMG has also been called "motor unit" EMG to distinguish it from "kinesiological" EMG.

The needle electrode needs to be placed appropriately in the target muscle. The levator ani muscle can be located by transrectal or transvaginal palpation and reached transcutaneously. The anal sphincter is easily located. The urethral sphincter is anatomically separate from the pelvic floor musculature and can be approached either perineally with a needle insertion 0.5 cm laterally to the urethral orifice (the authors suggest one single skin insertion per side) or it can be reached transvaginally using a Sims speculum to retract the posterior vaginal wall. The latter approach has been estimated as less uncomfortable [19], but is not used by many. The position of the needle should be adjusted in a systematic way so that the same muscle area is not repeatedly sampled.

The needle electrode most commonly used in diagnostic EMG is the single-use disposable CNE; it consists of a central insulated platinum wire encased within a steel cannula and the tip ground to give an elliptical area of 580–150 μm (Figure 36.1). This type of electrode has the recording characteristics necessary to record spike or near activity from about 20 muscle fibers. The number of motor units recorded therefore depends both upon the local arrangement of muscle fibers within the motor unit and the level of contraction of the muscle [2].

The other EMG technique (using a different needle electrode) to differentiate between normal and neuropathic muscle is single-fiber EMG (SFEMG). This method has often been used in research, particularly by British authors, but is not routinely applied in diagnostics.

Recently, surface EMG recording using noninvasive electrode arrays and multichannel EMG amplifiers was introduced to the EAS and puborectalis. Although observations in normal and pathological conditions have been published [20], the clinical value of this method in diagnosing neurogenic sacral disorders has not yet been demonstrated.

Normal Findings in Concentric Needle EMG Electrode

CNE EMG can provide information on insertion activity, abnormal spontaneous activity, MUPs, and interference pattern [2].

In healthy skeletal muscle, initial placement of the needle elicits a short burst of “insertion activity” that is due to mechanical stimulation of excitable membranes. This phenomenon may also be seen in the sphincters; however, because of the reflex, pain-induced burst of motor units that occurs, insertion activity may be difficult to discern. Insertion activity is recorded at a sensitivity setting of 50 μV/division, which is also the gain used to record spontaneous activity. The absence of insertion activity with an appropriately placed needle electrode usually indicates a complete denervation atrophy of the examined muscle.

There are two distinct patterns of electrical activity reported in the sphincter muscle. One is the tonic discharge observed at rest characterized by regular firing of MUPs. The degree of tonic discharge from the sphincter muscles varies in each individual and with posture. During sleep, this continuous firing diminishes but never disappears. The number of continuously active MUPs during relaxation can be estimated by counting the number of continuously firing low-threshold MUPs. In partially denervated sphincter muscle, there is—by definition—a loss of motor units (MUs). In patients with cauda equina or conus medullaris lesions, for instance, fewer MUPs fire continuously during relaxation, probably due to partial axonal loss.

The other is the phasic bursts of MUPs that may occur reflexly and evoked by various stimuli such as eliciting the anal reflex and by voluntary efforts such as coughing. Thus, in addition to continuously firing low-threshold motor units, new (high-threshold) MUPs are recruited (voluntarily or reflexly). Normally, MUPs should intermingle to produce an “interference” pattern on the oscilloscope during voluntary muscle contraction and during a strong cough.

It has been shown that the two MUP populations (the “tonic” and the “phasic”) differ in their characteristics, reflexly or voluntarily activated high-threshold MUPs being larger than continuously active “low-threshold MUPs.” As a consequence, a standardized level of activity at which a template-based multi-MUP analysis obtains between three and five MUPs on a single muscle site was suggested [21]. The main obstacle to qualified assessment of a reduced number of activated MUs, and activation of MUs at increased firing rates (as occurs in limb muscles), is a lack of concomitant measurement of the level of contraction of the examined muscle (this can be readily assessed when studying limb muscles).

MUPs should be analyzed at a sensitivity setting that allows their full display. The commonly used time scale is 5 or 10 ms/division, with an amplitude gain of 50–500 μV/division (Figure 36.6). The commonly used amplifier filter settings for concentric needle EMG (CN EMG) are 10–10,000 Hz. The amplitude of a MUP is largely determined by the activity of those muscle fibers closest to the recording electrode. Other fibers within a 0.5 mm radius of the recording electrode contribute little to the amplitude, but in a normal motor unit, there are unlikely to be more than two or three fibers belonging to the same motor unit. Amplitude is highly sensitive to needle position and very minor adjustments of the electrode will result in major changes, i.e., a change in position by 0.5 mm alters the amplitude 10- to 100-fold [2].

The duration of a motor unit is the time between the first deflection and the point when the waveform finally returns to the baseline. This will depend on the number of muscle fibers within the motor unit and is little affected by the proximity of the recording electrode to the nearest fiber. The difficulty with this measurement is defining the exact point of return to the baseline. The phases of a MUP are defined by the number of times the potential crosses the baseline. A unit that has four phases or more is said to be polyphasic. A related parameter is a "turn," which is defined as a shift in direction of a potential of greater than a specified amplitude.

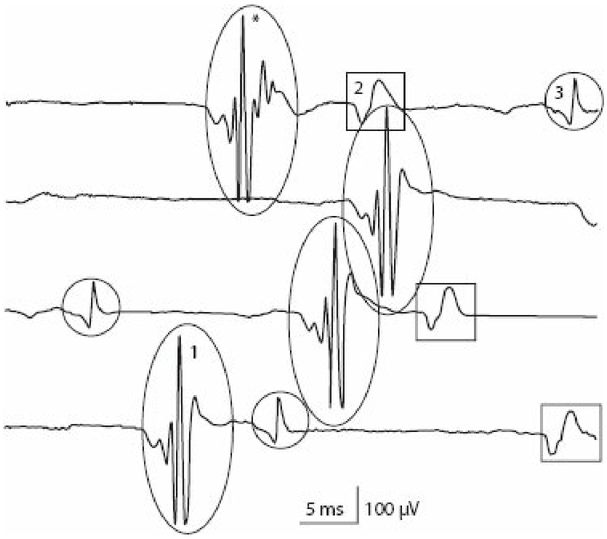

Figure 36.6 Concentric needle EMG recording of motor unit potentials from the urethral sphincter of a 35-year-old stress incontinent female, several years after second vaginal delivery. At this detection site, three motor unit potentials are firing continuously and can be analyzed. It can be seen that the motor unit potential (MUP) with the asterisk is different from the others of similar overall shape. Further analysis of such a signal is needed to ascertain whether it is a superimposition of two individual MUPs or an instability within a complex of MUPs. The use of trigger and delay facility is advantageous to solve such questions.

Using the standard recording facilities available on all modern EMG machines, individual MUPs can be captured and their amplitude and duration measured. To allow identification of MUPs and to be certain the late components of complex potentials are not due to superimposition of several MUPs, it is necessary to capture the same potential repeatedly (Figure 36.7). MUPs are mostly below 1 mV in the normal urethral sphincter and below 2 mV in the normal anal sphincter. Most are less than 7 ms, and few (less than 15%) are above 10 ms in duration. Additionally, most are bi- and triphasic, but up to 15%–33% may be polyphasic. Normal MUPs are stable—their shape on repetitive recording does not change [16,22].

There are two approaches to analyzing the bioelectrical activity of motor units quantitatively: either individual MUPs are analyzed or the overall activity of intermingled MUPs (the "interference pattern," or IP) is analyzed. Generally, three techniques of MUP analysis ("manual-MUP," "single-MUP," and "multi-MUP") and one technique of IP analysis (turn/amplitude, or T/A) are available on advanced EMG systems. By either method, a relevant sample of EMG activity needs to be analyzed for the test to be valid. In the small half of the sphincter muscle collecting 10 different MUPs has been accepted as the minimal requirement for using single-MUP analysis.

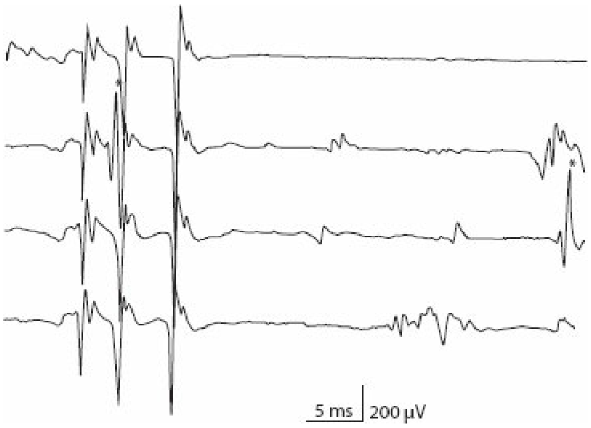

Figure 36.7 A concentric needle EMG recording from the urethral sphincter of an 18-year-old nulliparous female 4 years after a partial cauda equina injury. A trigger and delay facility is used. A complex motor unit potential (MUP) with prolonged duration is shown. Superimposition of another individual MUP (asterisk) may be falsely interpreted as instability of the potential.

Using manual-MUP and multi-MUP techniques, sampling of 20 MUPs (standard number in limb muscles) from each external anal sphincter (EAS) presents no difficulty in healthy controls and most patients. Normative data obtained from the EAS muscle by standardized EMG technique using all three MUP analysis techniques (manual-MUP, single-MUP, multi-MUP) have been published [23,24]. The technical differences in the methods are many and no in-depth description is attempted here. The more technical issues of quantitative EMG, the relevance and usefulness of various parameters, etc., are discussed in neurophysiological sources.

MUPs are identified either using a trigger and delay line (“single-MUP”) or appearing repeatedly in a prolonged recording of EMG activity (“manual-MUP”). Both approaches favor identification of relatively larger MUPs and become less reliable on stronger activation of muscle. Both methods are relatively slow and subject to examiner bias. The template-based multi-MUP analysis and the T/A analysis of IP (both run by automated computer analysis) are fast (5–10 and 2–3 minutes/muscle, respectively) and easy to apply and allow little opportunity for examiner bias [24]. Use of quantitative MUP and IP analyses of the EAS is facilitated by the availability of normative values that can be introduced into the EMG system’s software. It has been shown that normative data are not significantly affected by age, gender, number of uncomplicated vaginal deliveries, mild chronic constipation, and the part of the EAS muscle (i.e., subcutaneous or deeper) examined [25–27]. This makes quantitative analysis much simpler and results from different laboratories easily comparable.

The main drawback of the multi-MUP method is its tendency to chop up long polyphasic MUPs (such as occur in anal sphincter of MSA patients) into “components,” thus “missing” these highly abnormal MUPS. If the electromyographer checks the native EMG and observes such MUPs, the “collected MUPs” should be carefully scrutinized, and possibly, a “manual-MUP” analysis performed for a quality check.

Similar in-depth analyzed normative data from standardized techniques for other pelvic floor and perineal muscles are not yet available, but individual laboratories use their own normative data.

Single-Fiber Electromyography

SFEMG is used in general clinical neurophysiological laboratories to diagnose disturbed neuromuscular transmission (as in myasthenia gravis). The original recording needles are specially constructed (with a small recording area oriented “sideways” on the thin cannula; Figure 36.1) and very expensive and disposable versions are not available. An adapted method using disposable CNEs is being used in many laboratories as it is becoming unacceptable not to use disposable needles. When recording SFEMG, the amplifier filters are set so that low-frequency activity is eliminated (500 Hz to 10 kHz). Thus, the contribution of each muscle fiber appears as a biphasic positive–negative action potential.

In the past, SFEMG has been used to record not only the neuromuscular “jitter” (a measure of neuromuscular transmission) but also “fiber density” (FD), which is the mean number of muscle fibers belonging to an individual motor unit per detection site (a parameter that reflects motor unit morphology). To measure FD, recordings from 20 different detection sites are necessary (Figure 36.8) and the number of component potentials to each motor unit is recorded and averaged. The normal fiber density for the anal sphincter is below 2.0 [28,29]. Small changes with age have been reported; women have significantly greater fiber density than men [28].

Due to its technical characteristics, a SFEMG electrode is able to record even small changes that occur in motor units due to reinnervation, but is less suitable to detect changes due to denervation itself, i.e., abnormal insertion and spontaneous activity. SFEMG has indeed never been used in "routine uro-neurophysiological diagnostics," only in research.

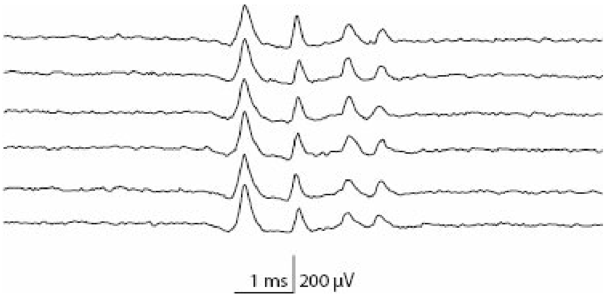

Figure 36.8 Single-fiber EMG recording from the anal sphincter of a 51-year-old nulliparous female with an extrapyramidal syndrome and recent development of poor bladder emptying accompanied by stress incontinence. The fiber density in the anal sphincter was found to be 3.7 and a diagnosis of possible multiple system atrophy was suggested. Further development of the clinical picture supported the diagnosis.

EMG Findings due to Denervation and Reinnervation

After complete denervation, all motor unit activity ceases and there may be electrical silence for several days. Between 10 and 20 days after a denervating injury, "insertion activity" becomes more prolonged and abnormal spontaneous activity in the form of short biphasic spikes ("fibrillation potentials") and biphasic potentials with prominent positive deflections ("positive sharp waves") appear [38]. In perineal muscles, complete denervation can be observed after traumatic lesions to the lumbosacral spine and damage to the cauda equina. Most lesions will, however, cause only partial denervation. In partially denervated muscle, some MUPs remain and mingle eventually with abnormal spontaneous activity. As the MUPs in sphincter muscles are also short and mostly bi- or triphasic, it requires considerable EMG experience to recognize abnormal spontaneous activity in the presence of surviving motor units. In long-standing partially denervated muscle, a peculiar abnormal insertion activity appears, the so-called repetitive discharges. These are made up of repetitively firing groups of potentials with so little jitter between the potentials that it is assumed the activity must be due to ephaptic or direct transmission of impulses between muscle fibers [30]. However, this activity may be found in the striated muscle of the urethral sphincter without any other evidence of neuromuscular disease and it has been hypothesized that it causes impaired relaxation of the muscle when spontaneous and profuse [31].

Abnormal spontaneous activity has also been described as a marker for degeneration of Onuf's nucleus occurring in patients with multiple system atrophy (MSA) [32].

After complete denervation, axonal reinnervation may occur and MUPs appear again, first short bi- and triphasic, soon becoming polyphasic, serrated, and of prolonged duration.

In partially denervated muscle, there is a certain loss of the number of motor units; some MUPs remain; however, the amount is difficult to estimate as the amount of motor unit activity recorded depends on needle position and voluntary activation. In partially denervated muscle, collateral reinnervation takes place; surviving motor axons will sprout and grow out to reinnervate those muscle fibers that have lost their nerve supply, resulting in a change in the arrangement of muscle fibers within the unit. Whereas in healthy muscle, it is unusual for two adjacent muscle fibers to be part of the same motor unit, following reinnervation several muscle fibers all belonging to the same motor unit come to be adjacent to one another. Early in the process of reinnervation, the newly outgrown motor sprouts are thin and therefore conduct slowly so that the time taken for excitatory impulses to spread through the axonal tree is abnormally prolonged. This is reflected by prolongation of the waveform of the MUP that may have small, late components (Figure 36.7). Neuromuscular transmission in these newly grown sprouts may also be insecure so that the motor unit may show “instability.” In skeletal muscle, with time and provided there is no further deterioration in innervation, the reinnervating axonal sprouts increase in diameter and thus increase their CV so that activation of all parts of the reinnervated motor unit become more synchronous. This has the effect of increasing the amplitude and reducing toward normal the duration of the MUPs measured with a CNE. This phenomenon may be different in the sphincter muscles where long duration motor units seem to remain a prominent feature of reinnervated motor units [33]. There are several conditions in which gross changes of reinnervation may be detected in motor units of the pelvic floor.

Sphincter EMG in the Evaluation of Suspected Cauda Equina Lesions

Injury to the cauda equina most commonly occurs following trauma, disc prolapse, and tumors. Sacral root damage results in pelvic floor dysfunction and patients present with lower urinary tract dysfunction (LUTD) and often sexual and bowel dysfunction as well. Concentric needle EMG of the external anal sphincter, innervated by the sacral 2, 3, and 4 roots, often demonstrates changes of chronic reinnervation, with a reduced interference pattern and enlarged polyphasic motor units (>1 mV amplitude), and is characteristic of long-standing cauda equina syndrome [34,35]. Though EMG may demonstrate pathological spontaneous activity 3 weeks or more after injury, these changes of moderate to severe partial denervation or complete denervation often become lost in the tonically firing motor units of the sphincter, and rather, an EMG of the bulbocavernosus muscle might detect these changes.

Sphincter EMG in the Diagnosis of Multiple System Atrophy

MSA, a variant of Parkinson’s disease, is a progressive neurodegenerative disease, which often, particularly in its early stages, is mistaken for Parkinson’s disease but is poorly responsive to antiparkinsonian treatment. Autonomic failure causing postural hypotension and cerebellar ataxia causing unsteadiness and clumsiness may be additional features. Urinary incontinence in both women and men occurs early in this condition, often appearing some years before the onset of obvious neurological features, and not uncommonly, patients may present to the urologist [36]. As part of the neurodegenerative process, selective loss of anterior horn cells occurs in Onuf’s nucleus so that partial but progressive denervation of the sphincter occurs and recorded motor units show changes of reinnervation, becoming markedly prolonged. Sphincter EMG has been demonstrated to be of value in distinguishing between idiopathic Parkinson’s disease and MSA [33,37]. The anal sphincter is once again most often studied and changes of chronic reinnervation in MSA tend to result in prolonged duration motor units and these changes can be detected easily [38].

The value of sphincter EMG in the differential diagnosis of Parkinsonism has been widely debated over the years. Technically, the MUPs recorded in MSA are quite prolonged and adopting a multi-MUP method results in a tendency to chop up these long polyphasic MUPs into individual components. Thereby, the late components might be missed when measuring the motor unit duration and the duration of the MUP may be erroneously noted as being normal. It is preferable therefore to identify MUPs manually when performing the EMG for a patient with suspected MSA to avoid this pitfall. Moreover, the changes are not specific to MSA and similar changes of chronic reinnervation may be found in long-standing Parkinson’s disease, other parkinsonian syndromes such as progressive supranuclear palsy [39] and dementia with Lewy bodies, and other neurodegenerative conditions such as spinocerebellar ataxia type 3, following obstetric injury with sphincter damage and cauda equina damage. Nevertheless, a body of opinion exists that maintains that a highly abnormal result in a patient with mild Parkinsonism is of value in establishing a diagnosis of probable MSA [40]. A highly abnormal EMG in the absence of other obvious causes in a patient with suspected MSA in first 5 years is significant [41].

EMG Changes after Vaginal Delivery: EMG in Idiopathic Incontinence

Electrophysiological methods have played a major role in establishing the neuromuscular lesion due to vaginal delivery as a risk factor for incontinence and pelvic organ prolapse (in addition to histopathological findings) [42]. Studies using computer-assisted quantified and less operator-biased techniques have confirmed older findings [43,44] of at least subtle neurogenic pelvic floor muscle changes in parous women [25,45].

It is a common experience that EMG changes are more pronounced in the urethral sphincter and in women with complicated vaginal deliveries. The finding of decreased intramuscular nerve density in the female urethral sphincter, which correlates with decreased muscular tissue, provides validation for the reported EMG abnormalities [46]. The abnormalities demonstrated in external anal sphincter and pudendal nerves have been suggested to be of pathogenetic significance and also for idiopathic fecal incontinence [47]. The development of imaging techniques has improved the diagnosis of postpartum structural (anatomical) damage to pelvic floor structures (including sphincters), which has put the importance of the postpartum neurogenic electrophysiological changes in perspective, which, when minor, may have little functional consequences.

The neurogenic damage caused by vaginal delivery is acknowledged to be, to a large extent, repaired by regenerative processes, but may then recur in the long run [47]. Repetitive straining at stool due to constipation has been the main implicated pathogenetic mechanism for such chronic progression of the neuromuscular lesion. Indeed, prolongation of pudendal nerve terminal latency has been demonstrated after 1 minute of hard straining [48]. Cumulative damage to the pudendal nerve may occur in severe chronic constipation; our study in patients with mild chronic constipation failed, however, to reveal any neurogenic anal sphincter changes, as compared to nonconstipated controls [27].

On the other hand, myogenic changes in pelvic floor muscles after vaginal delivery were also reported [49].

The usefulness of EMG in individual patients with idiopathic incontinence is limited as its predictive value for treatment outcome has not been established. In routine diagnostics, CN EMG of pelvic floor muscles in women after vaginal delivery and/or with undefined urinary incontinence should be restricted to the rare cases in whom a substantial pudendal nerve or sacral plexus involvement is suspected [50].

EMG Changes in Women with Urinary Retention and Obstructed Voiding

For many years, it was said that isolated urinary retention in young women was due to psychogenic factors or was the first symptom of onset of multiple sclerosis. However, CN EMG in this group has demonstrated that many such patients have profuse complex repetitive discharges (CRDs) and decelerating burst (DB) activity in the urethral sphincter muscle [51]. The CRDs have a very characteristic sound quality over the loudspeaker on the EMG machine, similar to a helicopter or motorcycle engine. It is the DBs that produce the myotonic-like sound, which has been likened to underwater recordings of whales. The jitter between the CRD potentials is very small [30].

It was proposed that this pathological spontaneous activity leads to sphincter contraction, which endures during micturition and causes obstruction to flow. Positive proof of this has been demonstrated by combined CN EMG and kinesiological EMG analysis of a group of females with dysfunctional voiding [11].

The syndrome described by Clare Fowler is associated with polycystic ovaries (Fowler's syndrome) [51]. There may be some (as yet unidentified) hormonal susceptibility of the female striated urethral sphincter, which causes a loss of stability of the muscle membrane and permits ephaptic transmission to develop, manifest as CRDs. Sustained contraction of the urethral sphincter has an inhibitory effect on bladder afferents and efferents, resulting in loss of bladder sensation and urinary retention.

Although urethral sphincter EMG may indicate the presence of an abnormality, it is inevitably only a sample and it is difficult to know whether the abnormality is sufficient to account for the clinical finding of complete or partial urinary retention. The investigations that have proved to be useful as adjuncts to the EMG are measurement of the urethral pressure profile (UPP) and volume of the sphincter muscle estimated with ultrasound [52]. Young women with urinary retention due to the sphincter abnormality regularly have UPPs in excess of 100 cm H_2O.

The typical clinical presentation of this syndrome is of a young woman with either spontaneous onset of urinary retention or retention following some sort of operative intervention. The mean age of a series of women with this problem was 27 years; spontaneous onset appears to be more common in women under 30 [52]. Characteristically, the women present with a bladder capacity in excess of 1 L, and, although this may cause painful distension, they lack any expected sensations of urinary urgency. There may or may not be a history of infrequent voiding prior to the onset of urinary retention. These women are taught to do clean intermittent self-catheterization and commonly experience difficulties with this technique, in particular pain and difficulty in removing the catheter. Patients with Fowler's syndrome respond well to sacral neuromodulation [53]. The stimulation does not, however, cause a cessation of the abnormal EMG activity [54].

A strong association with opiates and the onset of urinary retention is something that has become apparent recently, and an important observation was that of all the women, tests showed that one third did have FS, but a quarter of the women with Fowler's syndrome were taking opiate medications [55]. A recent hypothesis is that the abnormal sphincter EMG activity (cause remains unknown) probably causes neurotransmitter changes in the spinal cord, which are brought about by the effect of naturally occurring opiates, and that Fowler's syndrome is the result of spinal cord intoxication by the body's endorphins or enkephalins.

Because CN EMG will detect changes of both denervation and reinnervation as occur with a cauda equina lesion, as well as abnormal spontaneous activity, it has been argued that this test is mandatory in women with urinary retention [56]. It should certainly be carried out before stigmatizing a woman as having "psychogenic urinary retention."

EMG Changes in Primary Muscle Disease

CN EMG changes reflect pathological changes in the structure of the motor unit but also changes due to disease of the muscle fibers. With degeneration of muscle fibers, the motor units loose them; the number of motor units, however, may not change. The "typical" CN EMG features of myopathy of skeletal muscle are abundant small, low-amplitude polyphasic units recruited at mild effort. Such changes have not been reported in the pelvic floor, even in patients known to have generalized myopathy [57]. Pelvic floor muscle involvement in limb-girdle muscular dystrophy in a nulliparous female has been reported, but concentric needle EMG of her urethral sphincter was reported as normal [58]. Myopathic changes were observed in the puborectalis and the EAS in patients with myotonic dystrophy.

Little is currently known about what might be expected of an EMG recording from traumatized muscle that has been subject to a severe stretch injury—as occurs during childbirth—but there may well be changes reflecting rupture of individual muscle fibers and injury to small intramuscular nerves.

Diagnostic Usefulness of EMG Methods

Both CN EMG and SFEMG have been employed in neurourological, urogynecological, and proctological research. In routine diagnostics, using CN EMG, an experienced examiner can quickly come to a conclusion regarding normality or abnormality of the muscle examined simply by "observing" the abnormal spontaneous activity and the motor unit activity on the oscilloscope screen. This is one reason why quantified determination of MUP parameters by CN EMG is not as widely used as would be expected. If quantification is desirable, quantified CN EMG does provide the same information on reinnervation changes in muscle as the SFEMG parameter of "fiber density" [7,59]. An ideal quantitative EMG method has not been found yet, however, and expertise is required from the electromyographer to allow good quality control.

CN EMG is the electrophysiological method of choice in routine examination of skeletal muscle. It should be logical to extend an "EMG examination" from, for example, lumbar and upper sacral myotomes to the lower sacral myotomes in, say, a child with myelomeningocele or an adult after a cauda equina lesion. Furthermore, the concentric electrode can be employed at the same diagnostic session for recording motor evoked responses and/or reflex responses [21].

CONDUCTION STUDIES OF THE SACRAL MOTOR SYSTEM

Measurement of motor CV is routinely carried out to evaluate limb motor nerves. However, the technique requires access to stimulation of the nerve at two separated points and measurement of the distance between them (Figure 36.3)—a requirement that cannot be practically met in the pelvis. An electrophysiological parameter that requires a shorter length of motor nerve to be accessible is measurement of the terminal motor latency of a muscle response [2].

Terminal motor latency of the pudendal nerve can be measured by recording with a CNE from the bulbocavernosus, anal, or urethral sphincter muscles in response to bipolar stimulation placed on the perianal or perineal surface. The latencies of MEPs from the perineal muscles obtained by this means are between 4.7 and 5.1 ms [60]; similar latencies have been obtained for the same method of stimulation and recording from the anal sphincter [61,62].

The more widely employed technique of obtaining the pudendal terminal motor latency relies on stimulation with a special "surface electrode assembly" fixed on a gloved index finger [63], often referred to as the "St Mark's" device. It consists of a bipolar stimulating electrode fixed to the tip of the gloved finger with the recording electrode pair placed 5 cm proximally on the base of the finger. The finger is inserted into the rectum or vagina and stimulation is performed close to the ischial spine. A "rounded" response is recorded from the surface electrodes at the base of the finger (which is claimed to be the M wave from the external anal sphincter) with a typical latency around 2 ms. This test is usually referred to as the "pudendal nerve terminal motor latency (PNTML) test." If a catheter-mounted electrode is used, responses from the urethral sphincter can also be obtained. In studies, as a rule only latencies have been studied as amplitudes of the "M wave" response have not proved contributory. From studies using this test, it was concluded that occult damage to the pudendal innervation of the external anal sphincter occurs after vaginal delivery, and the conditions worsen over many years by abnormal straining patterns of defecation [47]. It was said to be of pathogenetic importance for idiopathic stress urinary incontinence, fecal incontinence, and pelvic floor prolapse [44]. Sultan et al. [64] also demonstrated a small but statistically significant increase in pudendal nerve latency following vaginal delivery, but, more importantly, they demonstrated a defect of either the internal or external anal sphincter, or both, in 35% of women after vaginal delivery using anal endosonography and a strong association between these defects and the development of bowel symptoms. The prolonged latency and the muscle defect were thought to reflect a common traumatic cause.

Although no correlation of PNTML to parity was found in some studies [28], the term "pudendal neuropathy" has become established in the literature for a while, and authors less familiar with clinical neurophysiology theory tended to equate a prolongation of pudendal motor latency with pelvic floor denervation. This however, is mistaken, as prolongation of latency is a poor measure of denervation. In fact, experts now mostly doubt the validity of the test. A lack of correlation to sphincter pressure measurements has been demonstrated: in one study, approximately 50% of patients with PNTML had normal anal canal squeeze pressures [65]. In contrast to earlier studies, more recent work suggests the test does not predict improvement, or the lack of improvement, after surgical repair of anal sphincter defects [66]. A prospective evaluation of anorectal physiological tests in 90 patients with fecal incontinence did not find that pudendal terminal latency test results changed treatment decisions [67]. Indeed, the American Gastroenterological Association statement indicated that "pudendal terminal latency cannot be recommended for evaluation of patients with fecal incontinence" [68]. Recording of PNMTL is no longer recommended in the investigational workup of the patient with suspected pudendal neuralgia. There are several reasons for this. Nerve entrapment initially results in axonal excitability and excessive ectopic spike discharges that is followed by central sensitization, which plays an important role in maintaining chronic pain. These functional changes cannot be identified by clinical neurophysiology and only when entrapment is severe enough do abnormalities appear. Segmental demyelination results in conduction block with focal nerve conduction slowing, which may not be identified in the short length of the pudendal nerve measured. Also, these techniques investigate motor functions, whereas symptoms and signs are mainly due to sensory dysfunction [69]. Currently, measuring pudendal nerve latencies in incontinence is not recommended [70].

A selective needle recording of a (sphincter or pelvic floor) muscle response (M wave) on appropriate electrical stimulation may be informative in selected patients with suspected "lower motor neuron–type" lesions.

Anterior Sacral Root (Cauda Equina) Stimulation

Transcutaneous stimulation of deeply situated nervous tissue became possible with the development of special electrical [71] and magnetic [72] stimulators. When applied over the spine, these stimulators stimulate mainly the roots at the exit from the vertebral canal [73]. There have been reports of these techniques applied to the sacral roots [74]. Parasympathetic efferents most probably cannot be stimulated using magnetic stimulation: while it has been claimed that MPEs from detrusor can be produced following magnetic stimulation of the cauda equina [75], others have demonstrated inhibition of detrusor hyperreflexia following sacral root stimulation [76], which is expected after depolarization of perineal afferents.

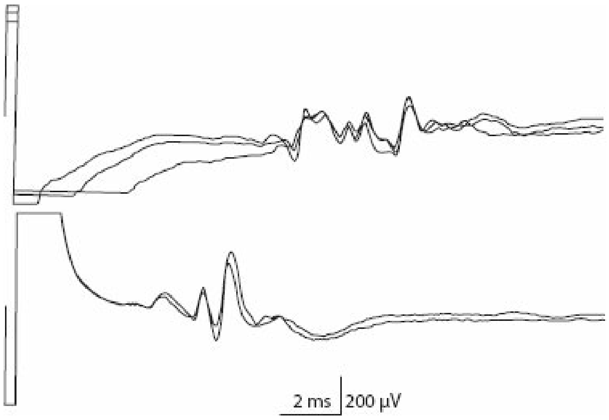

Figure 36.9 Concentric needle EMG recording from the anal sphincter showing responses on "strong" electrical stimulation with surface electrodes over the back (upper trace at level L1; lower trace at level S3). Digitimer stimulator: stimulus duration 50 µs, stimulus amplitude 50%. Three and two consecutive responses are superimposed, respectively.

Needle EMG electrodes rather than nonselective surface electrodes should be used to record MEPs to electrical or magnetic stimulation because both depolarize underlying neural structures in a nonselective fashion and there may be activation of several muscles innervated by lumbosacral segments. It has been shown that responses from gluteal muscles may contaminate attempts to record from the sphincters and lead to error [77].

Recording of MEPs with magnetic stimulation has been less successful, at least with standard coils [78,79], than with electrical stimulation, and there is often large stimulus artifact. Positioning of the ground electrode between the recording electrodes and the stimulating coil should decrease the artifact (Figure 36.9). Stimulation of the roots may be used to obtain a peripheral conduction time so that a central conduction time (see next section) can be calculated [79].

Demonstrating the presence of a perineal MEP on stimulation over the lumbosacral spine and recording this with a concentric needle (CN) EMG electrode may occasionally be helpful; however, an absent response has to be evaluated with caution and the clinical value of the test has yet to be established.

Assessment of Central Motor Pathways

Using the same magnetic or electrical stimulation as mentioned earlier, it is possible to stimulate the motor cortex and record a response from the pelvic floor. Magnetic stimulation is less unpleasant; electrical cortical stimulation is nowadays only used intraoperatively in anesthetized patients.

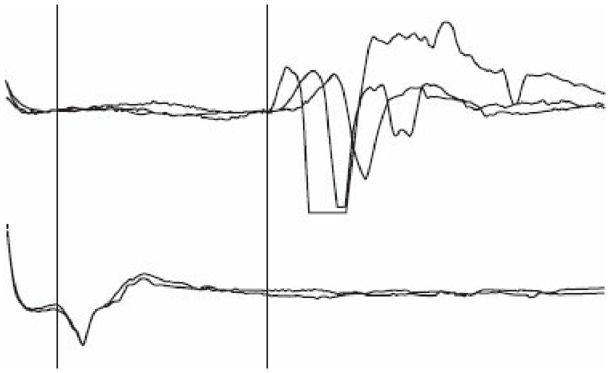

Figure 36.10 Recording from the urethral sphincter with a concentric needle electrode (CNE) in response to magnetic stimulation of the lower lumbar spine (lower trace; latency 6.5 ms) and the motor cortex (upper trace; latency 25.4 ms). The effect of "facilitation" (i.e., a slight voluntary contraction) on shortening the latency of the response following cortical stimulation is evident.

By electrical stimulation over the motor cortex of healthy subjects, MEPs in anal and urethral sphincters and in the bulbocavernosus [77] muscles were reported. The mean latencies were between 30 and 35 ms if no "facilitatory maneuver" was used. If, however, stimulation was performed during a period of slight voluntary contraction of the muscle, the latencies of MEPs shortened significantly (for up to 8 ms) (Figure 36.10).

By applying stimulation both over the scalp and in the back (at level L1), and subtracting the latency of the respective MEPs, a "central conduction time" can be obtained. Central conduction times of approximately 22 ms without and about 15 ms with the facilitation (i.e., slight voluntary contraction) have been reported [79].

Substantially, longer central conduction time in patients with multiple sclerosis and spinal cord lesions as compared to healthy controls have been found [1], but all those patients had clinically recognizable cord disease.

Normative values for the urethral sphincter and the puborectal muscle in adult women have been reported for transcranial magnetic stimulation [80,81]. The necessity to use concentric needle EMG for recording has been reconfirmed [82].

MEPs have opened an avenue of research on excitability of the motor cortex. It has been demonstrated that in comparison to the motor area for hand muscles, the anal sphincter motor cortex has less intracortical inhibition [83].

Because of the significant influence of voluntary contraction, there is a possibility of variability of both total conduction times and central conduction times. A well-formed sphincter MEP with a normal latency in a patient with a functional disorder or a medicolegal case may on occasion be helpful.

MEP on cortex stimulation may be useful for intraoperative monitoring, and indeed, this may be the only routine application of this test at present [84].

CONDUCTION STUDIES OF THE SACRAL SENSORY SYSTEM

Cerebral Somatosensory Evoked Potentials (SEPs)

The pudendal evoked response is easily recorded following electrical stimulation of the clitoral nerve [79,85,86]. This SEP is of highest amplitudes at the central recording site ([Cz –2 cm: Fz] of the International 10–20 EEG System) and is highly reproducible. Amplitudes of the P40 measure between 0.5 and 12 μV [86] (Figure 36.11). Later negative (at around 55 ms) and then further positive waves are interindividually quite variable in amplitude and expression and furthermore have little known clinical relevance.

Pudendal SEP recordings have been widely employed in patients with neurogenic bladder dysfunction due to multiple sclerosis [78], but it has since been shown that the tibial cerebral SEPs are more often abnormal than the pudendal SEP, and only in exceptional cases is the pudendal SEP abnormal but the tibials normal, pointing to an isolated conus involvement [87]. Cerebral SEPs on clitoral stimulation were reported as a possibly valuable intraoperative monitoring method in patients with cauda equina or conus at risk of a surgical procedure [88,89].

Special techniques of stimulation isolate each dorsal clitoral nerve and may be more sensitive at locating the precise site of pathology [90]. Following spinal cord injury, tibial and pudendal SEPs have been claimed to predict recovery in bladder control [91]. Pudendal SEPs were used to study the mechanism of sacral neuromodulation [92].

A study that looked at the value of the pudendal evoked potential when investigating urogenital symptoms for detecting relevant neurological disease found it to be of lesser value than a clinical examination looking for signs of spinal cord disease in the lower limbs, i.e., lower limb hyperreflexia and extensor plantar responses [93]. There may, however, be circumstances in routine diagnostics—such as when a patient is complaining of loss of bladder or vaginal sensation—that it is reassuring to be able to record a normal pudendal evoked response.

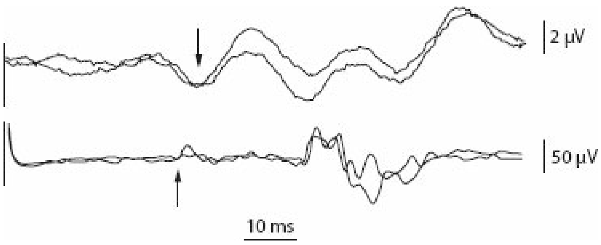

Figure 36.11 Cerebral somatosensory evoked potential (SEP) (above) and bulbocavernosus reflex (below) on dorsal clitoral nerve stimulation (rectangular pulses, 0.2 ms long at 1 Hz) in a 37-year-old woman with a compressive fracture of L1, complaining of difficulties in initiation of micturition. SEP is recorded with surface electrodes (Cz –2 cm: Fz); the bulbocavernosus reflex is recorded from the anal sphincter with surface electrodes. Two consecutive averages of 128 responses are superimposed. The P40 of the SEP and the first component of the bulbocavernosus reflex are indicated. The first reflex component is spurious at the applied stimulation strength, which was two-times sensory threshold; the second (late) reflex component is obvious.

Pudendal SEP may be useful for intraoperative monitoring, and indeed, this may be the only routine application of this test at present [84].

Electrical Stimulation of the Urethra, Bladder, and Anal Canal

Cerebral SEPs can also be obtained on stimulation of the bladder urothelium [94]. When making such measurements, it is of utmost importance to use bipolar stimulation in the bladder or proximal urethra; otherwise, somatic afferents will be depolarized [95,96]. These cerebral SEPs have been shown to have a maximum amplitude over the midline (Cz –2 cm: Fz) [95]; but the potential is of low amplitude (1 µV or less) and of variable configuration and may be difficult to identify in some control subjects [95,97]. The typical latency of the most prominent negative potential (N1) is approximately 100 ms [95,97]. The responses were claimed to be of more relevance to neurogenic bladder dysfunction than the pudendal SEP, as the Aδ delta sensory afferents from bladder and proximal urethra accompany the autonomic fibers in the pelvic nerves [95].

Another stimulation site in the perineal region is the anal canal, following which cerebral SEPs with a slightly longer latency than those obtained following stimulation of the clitoris have been reported, but it is not possible to record this response from all control subjects. The rectum and sigmoid colon have also been stimulated, and cerebral SEPs of two types recorded. One was similar in shape and latency to pudendal SEP and the other to SEP recorded on stimulation of bladder/posterior urethra [98].

SACRAL REFLEXES

Physiological Background, Methods, and Terminology

“Sacral reflexes” refer to electrophysiologically recordable responses of perineal/pelvic floor muscles to (electrical) stimulation in the urogenitoanal region. There are two reflexes—the anal and the bulbocavernosus—that are commonly clinically elicited in the lower sacral segments; both have the afferent and efferent limb of their reflex arc in the pudendal nerve and are centrally integrated at the S2–S4 cord levels (Figure 36.11). Electrophysiological correlates of these reflexes have been described. EMG recording of the sacral reflex has been shown to be more reliable than the clinically assessed response (e.g., observing and palpating the contraction) in males and particularly in females [99].

It is possible to use electrical [60], mechanical [100], or magnetic stimulation. Electrical stimulation can also be applied perianally [60]. The pudendal nerve itself may be stimulated by applying needle electrodes transperineally [101] or by using “St Mark’s electrode” [102]. As a rule, reflex responses are recorded as EMG activation of target muscles, but responses of the external urethral sphincter have also been recorded with a microtip transducer catheter as pressure rises, with latencies between 27 and 41 ms [103].

Bladder neck/proximal urethra can be stimulated using a catheter-mounted ring electrode [96] and reflex responses obtained from perineal muscles. These reflexes have been referred to as “vesicourethral” and “vesicoanal,” depending from which muscle the reflex response is recorded. With visceral denervation (e.g., following radical hysterectomy), the viscerosomatic reflexes (from both bladder and urethral stimulation) may be lost while the bulbocavernosus reflex is preserved. Loss of bladder–urethral reflex with preservation of bladder–anal reflex has been described with urethral afferent injury after recurrent urethral surgeries [104].

Reports of sacral reflexes obtained following electrical stimulation of clitoral nerve give consistent mean latencies of between 31 and 38.5 ms [60]. Sacral reflex responses obtained on perianal or bladder neck/proximal urethra stimulation have latencies between 50 and 65 ms [60]. This more prolonged response is thought to be due to the afferent limb of the reflex being conveyed by thinner myelinated nerves with slower conduction velocities than the thicker myelinated pudendal afferents. The longer latency "anal reflex"—the contraction of the anal sphincter on stimulation of the perianal region—may also have thinner myelinated fibers in its afferent limb as it is produced by a nociceptive stimulus. On stimulation perianally, a short latency potential can also be recorded as a result of depolarization of motor branches to the anal sphincter [60,61] (being an "M wave").

Sacral Reflex on Electrical Stimulation of Penis or Clitoris

The nomenclature of the various reflex responses that can be recorded from pelvic structures in response to electrical stimulation was recently rationalized so that the term used gives an indication as to the site of stimulation and recording. The penilo-cavernosus/clitoro-cavernosus reflex, formally known as the "bulbocavernosus" reflex, assesses the sacral root afferent and efferent pathways. The dorsal nerve of penis (or clitoris) is electrically stimulated and recordings are made from the bulbospongiosus (previously called bulbocavernosus) muscle (or the EAS) usually with a concentric needle. This reflex was shown to be a complex response, often formed by two components [60,105]. The first component (with typical latency of about 33 ms) is the response that has been most often called the bulbocavernosus reflex. It is stable, does not habituate, and is thought to be an oligosynaptic reflex response, as the variability of single motor neuron discharges within this reflex is similar to that of the first component of the blink reflex [105]. The second component has a similar latency to the sacral reflexes evoked by stimulation perianally or from the proximal urethra. The variability of single motor neuron responses within this component is much larger, as is typical for a polysynaptic reflex [105]. The second component is not always demonstrable as a discreet response. The two components of the reflex may behave somewhat differently in control subjects and in patients: whereas in normal subjects it is usually the first component that has a lower threshold, in patients with partially denervated pelvic floor muscles, the first reflex component cannot be obtained with single stimuli, but on strong stimulation, the later reflex component does occur. This can cause confusion, and very "delayed" reflex responses may be recorded in patients without recognizing the possibility that it is not a delayed first component but an isolated second component of the reflex. The situation can be clarified by using double stimuli that facilitate the reflex response and may reveal the first component, which was not obvious on stimulation with single stimuli [106].

Sacral reflex responses recorded with needle or wire electrodes can be analyzed separately for each side of the anal sphincter; this is important because unilateral or asymmetrical lesions are common. Special techniques of stimulation isolate each dorsal clitoral nerve and may be more sensitive for identifying pathology [90]. Using unilateral dorsal penile nerve blocks, the existence of two unilateral bulbocavernosus reflex arcs has been demonstrated [107,108]. Thus, by detection from the left and right bulbospongiosus (and probably also the EAS) muscles, separate testing of right and left reflex arcs can be performed. In cases of unilateral (sacral plexopathy, pudendal neuropathy) or asymmetrical lesions (cauda equina), a healthy reflex arc may obscure a pathological one.

Sacral reflex responses on stimulation of the clitoral nerve have been proposed as being valuable in patients with cauda equina and lower motor neuron lesions; however, a reflex with a normal latency does not exclude the possibility of an axonal lesion in its reflex arc. Although most reports deal with abnormally prolonged sacral reflex latencies, it was suggested that a very short reflex latency may indicate the possibility of a tethered cord [109], the shorter latency being attributed particularly to the low location of conus. Shorter latencies of sacral reflexes in patients with suprasacral cord lesions were also reported. Continuous intraoperative recording of sacral reflex responses on clitoris stimulation is feasible if double pulses [110] or a train of stimuli are used and has become established in some neurosurgical centers focusing on lower spine surgery [84].

Sacral Reflex on Mechanical Stimulation

Mechanical stimulation has been used to elicit the bulbocavernosus reflex in both sexes [111], but there is as yet little experience with female patients. Either a standard commercially available reflex hammer or a customized electromechanical hammer can be used [97]. Such stimulation is painless and can be used in children or patients with pacemakers in whom electrical stimulation is contraindicated.

Diagnostic Usefulness of Sacral Reflex Testing

Sacral reflex testing should be a part of the "diagnostic battery," of which concentric needle EMG exploration of the pelvic floor muscles is the most important part [21]. Measurement of sacral reflexes is established and carried out in laboratories worldwide and is—apart from EMG—the most time-honored uroneurophysiological diagnostic procedure.

In those subjects, in whom the penilo-cavernosus/clitoro-cavernosus reflex is difficult to elicit, double electrical stimuli should be used. A complete reflex arc lesion should not be inferred by absence of a response if only single pulse is used for stimulation [35].

Penilo-cavernosus/clitoro-cavernosus reflex testing is suggested as a complementary test to CNEEMG examination of pelvic floor muscles in patients with suspected peripheral nervous lesions [112].

However, the expectation of some authors that, with measurement of sacral reflexes, a single, easily learned test could distinguish between neurogenic and nonneurogenic sacral dysfunction was unrealistic. Although testing reflex responses is a valid and useful method to assess integrity of reflex arcs, and electrophysiological assessment of sacral reflexes is a more quantitative, sensitive, and reproducible way of assessing the S2–S4 reflex arcs than any of the clinical methods, uncritical interpretation of results should be discouraged.

AUTONOMIC NERVOUS SYSTEM

The uroneurophysiological methods discussed so far assess only the myelinated fibers, whereas it is the autonomic nervous system, and the parasympathetic component in particular, that is most relevant for sacral organ function. It has been argued that local involvement of the sacral nervous system (such as trauma, compression, etc.) will usually involve somatic and autonomic fibers simultaneously. However, as there are some local pathological conditions (such as mesorectal excision of carcinoma or radical hysterectomy) that can cause a pure autonomic lesion, methods by which the parasympathetic and sympathetic nervous systems innervating the pelvic viscera could be assessed directly would be very helpful. Information on parasympathetic bladder innervation can, to some extent, be obtained by cystometry, but direct electrophysiological testing would be desirable. In cases where a general involvement of thin fibers is expected, an indirect way to examine autonomic fibers is to assess thin sensory fiber function. As unmyelinated afferent fibers transmit temperature sensation and pain, unmyelinated fiber neuropathy can be identified by testing thermal sensitivity. Thin (visceral sensory) fibers are tested by stimulating the proximal urethra or bladder and recording sacral reflex responses or cerebral SEPs.

Sympathetic Skin Response

The sympathetic nervous system mediates sweat gland activity in the skin, and changes in this activity lead to changes in skin resistance. On "stressful stimulation," a potential shift can be recorded with surface electrodes from the skin of the palms and soles and has been reported to be a useful parameter in the assessment of neuropathy involving unmyelinated nerve fibers [113]. The response (sympathetic skin response [SSR]) can also be recorded from perineal skin [114]. The SSR is a reflex that consists of myelinated sensory fibers, a complex central integrative mechanism, and a sympathetic efferent limb (with postganglionic nonmyelinated C-fibers).

The stimulus used in clinical practice is usually an electric pulse delivered to the upper or lower limb (to mixed nerves), but the genital organs can also be stimulated [114]. The responses are easily habituated and depend on a number of endogenous and exogenous factors including skin temperature, which should be at least above 28°C. The latencies of SSR on the penis following stimulation of a median nerve at the wrist could be obtained in all normal subjects [114]. No equivalent control data exist in women as yet.

Limited literature exists regarding the relationship between SSR results and bladder dysfunction. One study reports that diabetic cystopathy was associated with autonomic neuropathy as detected by SSR [115]. A correlation has been shown between the absence of the SSR response in foot and bladder neck dyssynergia following spinal cord injury [116]. Recording from the perineal region increases the diagnostic sensitivity for assessing sympathetic nerve function within the thoracolumbar cord [117].

The test is not sensitive for partial lesions as only complete absence of response has been regarded as abnormal. Its utility in evaluating bladder and urethral dysfunction is not yet established.

CONCLUSIONS

In routine diagnostics, uroneurophysiological testing is becoming established in patients with (suspected) peripheral nervous system lesions, where particularly (quantitative) concentric needle EMG and recording the clitoro-cavernosus (bulbocavernosus) reflex is recommended as standard (and standardized) procedure in selected patients, particularly if they are candidates for invasive therapeutic procedures [21,112]. It has been demonstrated that both techniques are indeed complementary and have —performed in the same patient—a higher sensitivity than each test on its own (i.e., 96%) [118].

Uroneurophysiological techniques continue to be useful in research and may become more relevant in the future for intraoperative identification and monitoring of nervous structures.

37 Imaging of the Upper and Lower Urinary Tract: Radiology and Ultrasound

Andrea Tubaro, Kirsten Kluivers, Federica Puccini, and Antonio Carbone

INTRODUCTION

This chapter will review indications, techniques, and results of radiological (x-ray) and ultrasound (US) imaging of the upper urinary tract (UUT) and lower urinary tract (LUT) in women with LUT dysfunction (LUTD). Although some of the techniques may be considered based on their historical contribution, a knowledge of radiological imaging and the information obtained from these images remains an important part of the development of our understanding of pelvic anatomy and function. The crux of clinical research and ultimately clinical practice concerned with imaging in urinary incontinence (UI) and POP is to establish that there is a clinical benefit to the measurements that are obtained. Imaging is a method to evaluate anatomy of the individual patient and to diagnose conditions depending on the morphological or functional modifications of individual organs or structures. Imaging can confirm or augment the findings of physical examination and may provide information that is otherwise unattainable. The identification of the clinical scenarios in which this additional information is beneficial to the management of the patient is the ultimate measure of the utility of the study. Although we may postulate that intraobserver and interobserver variability of physical examination is higher when compared to imaging, this may not necessarily always be true, as well as the assumption that a correlate always exists between the two modalities.

Research into diagnostic accuracy is regulated by the standards for reporting of diagnostic accuracy initiative [1] although the recommendations are rarely adhered to in the (peer-reviewed) literature. The Oxford Centre for Evidence-Based Medicine introduced, in 2011, new criteria to grade the levels of evidence in manuscripts reporting studies on diagnostic tests [2]. The highest level of evidence according to the Oxford criteria is based on “systematic reviews of cross sectional studies with consistently applied reference standard and blinding” [2]. This is a paradigm change from the previous documents in which studies of diagnostic tests were not considered and proper evaluation of the available evidence is now possible.

The analysis of the literature related to the utility of imaging demonstrates that the evaluation of diagnostic accuracy is often performed properly and the available data include sensitivity and specificity as well as test–retest (intraobserver) and interobserver variability. Of note, a common problem is in the choice of a gold standard that most commonly is another imaging technique, physical examination or findings during surgical operation.

The problem in the comparison of imaging to physical examination is that whatever the outcome of the index test is, nobody can tell us whether the truth lies in what we can just speak about the concordance.

As long as imaging is considered an addition to physical examination, the goal may not be to show that there is a high level of agreement between the two, but rather to prove that adding imaging on top of physical examination results in a significant improvement in patient management and treatment outcome. Although it is easy to blame the investigators for a faulty study design, the reality is that designing a study on the clinical benefit of a new imaging technique in patients undergoing diagnostic studies or surgery is a very difficult problem because investigators deal with two different variables: the test under evaluation (e.g., US imaging of the pelvic floor) and the surgical procedure (e.g., surgery for anterior vaginal wall prolapse). In addition, large studies may be needed to evaluate the potential beneficial effects of imaging in certain subgroups of patients. Whenever the outcome of surgery is the primary outcome parameter, large multicenter studies are preferable, but when examining the literature in this area, most studies are relatively small and come from single institutions and the variability in patient selection, surgical technique, and outcome assessment must be taken into consideration.

Furthermore, a single positive study is rarely compelling enough to change standard practice and confirmatory studies are required. Moving from the identification of the gold standard to defining the best practice is a very long process but it remains the ultimate goal of studies on new imaging techniques.

Imaging of the pelvic floor in patients with UI and POP is limited by our lack of complete understanding of the physiopathology of these conditions. A classic historical example is the case of patients with stress UI (SUI). For decades, imaging techniques relied on x-ray imaging (e.g., voiding cystograms). This was based upon the assumption that quantification of the bladder neck mobility and the Green classification were of importance [3]. Further understanding of the anatomic relationships suggested alternative explanations and demonstrated the limitations of this technique [4–10]. Although the images confirmed the observations made during clinical examination and simplified evaluation of the patient in the standing position, specialists in the field demonstrated a diminished interest in the fluoroscopic imaging of SUI when selecting treatment alternatives, in part due to advances in surgical techniques. When new imaging modalities became available and techniques such as US imaging and MRI were introduced, research in the area of anatomy and anatomic relationships flourished again since not only the margins of the pelvic floor viscera but also images of the organs themselves together with the surrounding structures (muscles and fascias) could be obtained in x-ray imaging.

In recent years, US imaging of the pelvic floor rapidly replaced x-ray imaging because of technological improvements, availability in the office, low cost, lack of radiation hazard, and user-friendliness. Research in this area dates back to 1980 when US was first applied in patients with SUI [11]. Several papers investigated the relation between x-ray and US imaging [12–19], and the correlation between the two was found to be good [16], while US proved superior, particularly in obese women [19].

Although these data are certainly reassuring, they only suggest that US imaging can replace x-ray techniques but they do not establish any additional clinical utility. In contrast to CT scan and MRI, US imaging is not a “no-touch” technique. Interference between the exploring probe and the target tissue is unavoidable [20,21], although it can certainly be minimized. This is the reason why endocavitary imaging (transvaginal or transrectal) has been largely replaced by abdominal and perineal techniques. Since bony structures reflect the beam and affect the US images, but are required as reference points, abdominal imaging has been gradually replaced by perineal approach. Two-dimensional (2-D) cine loops or 3-D volumes may be acquired during imaging and can be reviewed offline at a later stage. Similar to CT or MRI techniques, nowadays, 3-D US images may be obtained through any plane. The depth of the perineal volumes in the cranial direction is, however, smaller in US compared with MRI, which may hamper imaging of the central compartment of the pelvic floor in US imaging [20]. The availability of high-speed computing made real-time or dynamic 3-D US imaging possible and is currently known as 4-D imaging. This technique has proved particularly interesting in the functional imaging of SUI and POP.

The lack of standardization in US imaging and MRI is impairing research in this area. Of note, there is no consensus regarding the ideal patient position (supine or standing) [22], picture orientation in US (caudal part on top [23] bottom, or right side of the picture [24]), reference lines in MRI [25], and degree of bladder filling (empty vs. full [26,27]). Furthermore, experience has demonstrated how difficult it is to standardize cough and Valsalva maneuvers, which is similarly a problem in all POP assessment tools [28,29].

In general, the challenge remains that our understanding of the physiopathology of UI and POP is still incomplete and the treatment methods currently applied for correction of the clinical conditions may not be significantly improved, in either selection or performance, by the information obtained by current imaging techniques or the research methods designed to demonstrate their utility.

IMAGING OF THE UPPER URINARY TRACT

The rationale for imaging the UUT in female patients with LUTD is twofold: to identify UUT malformations that may be associated with LUTD and to monitor the effect of LUTD on the UUT when necessary. Imaging of the UUT is always indicated in neurogenic UI, but in nonneurogenic LUTD, the imaging is rarely justified. In extraurethral UI, imaging of the renal moiety, which is sometimes dysplastic or ectopic, is of importance to plan adequate management and surgery. In myelodysplasia, elevated storage pressures in the urinary bladder can cause deterioration of the UUT with hydronephrosis and renal failure, and the kidney morphology and function must be monitored over time [30]. Severe POP may results in hydronephrosis because of angulation of the pelvic ureters by the uterine arteries (Figure 37.1) [31].

With the exception of these three conditions, there is no indication for UUT imaging in the nonneurogenic patient.

Imaging Techniques

Different imaging techniques can be used to picture the UUT: ultrasonography, x-rays, CT, MRI, and isotope scanning. In the absence of comparative data on their accuracy and clinical benefit in the management of patients with LUTD, the choice of the technique also depends on availability, expertise, and local policies. In general, the least expensive and hazardous techniques are recommended. Because of the low level of evidence available in the peer-reviewed literature on this subject, recommendations are generally based on expert opinion unless otherwise stated.

Ultrasonography

US is the standard technique for imaging the UUT because of its availability, low cost, and lack of x-ray exposure. Diagnosis of hydronephrosis is straightforward as the collecting system is normally hardly visible on US and imaging is more qualitative (hydronephrosis yes/no) rather than quantitative as there is no relation between the amount of UUT dilatation and the degree of obstruction, although there is a relation between the degree of dilatation and cortical damage [32]. Doppler analysis of interlobar and arciform arteries has been proposed to diagnose obstruction of the UUT although the technique never gained popularity [33]. In the presence of hydronephrosis, additional imaging is usually required to identify the cause and site of the obstruction. US imaging is ideal in the follow-up of patients with LUTD when UUT imaging must be repeated over time.

Intravenous Urography

This technique has been the cornerstone of UUT imaging for decades as it provides information on both renal anatomy and function. Indications are limited by the need of normal renal function (creatinine < 2.0 ng/dL) and no contraindications for the use of iodinated contrast agents [34]. Intravenous urography (IVU) is the first-line imaging modality for extraurethral incontinence although the renal unit associated with an ectopic ureter is, however, often small, poorly functioning, and ectopic and can sometimes be difficult to image unless delayed films and tomography are used (Figure 37.2) [35–37]. When the renal moiety cannot be imaged on IVU and CT, MRI or isotope scanning is recommended [38–40]. IVU is still recommended in case of ureterovaginal fistula although uro-CT and uro-MR can be also used, and dilatation of the UUT is observed in 84%–92% of fistula cases [41,42].

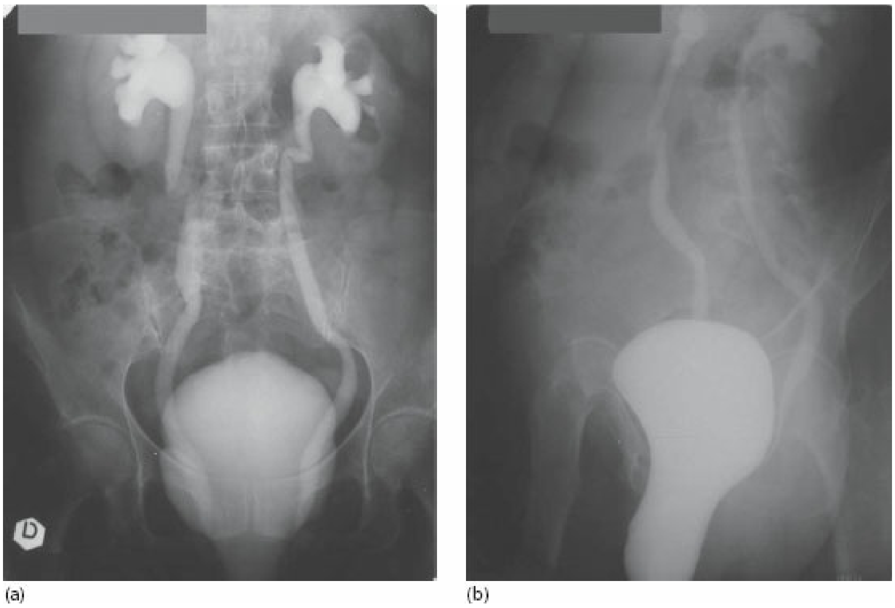

Figure 37.1 Intravenous pyelography. Bilateral hydronephrosis in a 54-year-old patient with grade IV genital prolapse: anteroposterior (a), oblique (b). (Courtesy of Prof. G. Tomiselli.)

CT and MRI

Both techniques have been recommended for the management of patients with a suspected ectopic ureter because of their ability to image small, poorly functioning renal moieties as well as the collecting system [43–46]. Both CT and MRI require normal renal function whenever contrast medium is used, and although MR contrast agents were considered safe, they may cause adverse effects [47–49].

Isotopes Scanning

Isotope scanning is mainly used to quantify function of the individual renal moieties and to locate ectopic or poorly functioning kidneys. Whenever renal function impairment is suspected and separate renal function must be quantified, isotope scanning is the technique of choice. The interpretation of isotope scanning is not always straightforward as there are various physiological factors and technical pitfalls that can influence the results. These include the choice of radionucleotide, timing of diuretic injection, state of hydration and diuresis, fullness or back pressure from the bladder, variable renal function, and compliance of the collecting system [50,51]. When an ectopic ureter is suspected, renal scintigraphy may be successful in imaging hypoplastic kidneys when other techniques have failed [52].

X-RAY IMAGING OF THE LOWER URINARY TRACT

For many years, x-ray imaging of the LUT has been performed in female patients with UI and POP whenever surgery was planned. The quantification of bladder neck mobility and pelvic organ descend was considered of importance for proper patient management, but a more strict evaluation of the available evidence failed to confirm any clinical benefit for most patients. X-ray imaging can sometimes help to identify coexisting conditions of the LUT such as bladder diverticula, urethral diverticulum, or comorbidities such as bladder stones, tumors, and foreign bodies (Figures 37.3 through 37.6). X-ray imaging in LUTD mainly consists of voiding cystourethrogram (VCUG) for the quantification of bladder neck mobility (Figures 37.7 and 37.8) or bladder prolapse (Figure 37.9); the opacification of the vagina and rectum has been proposed to achieve a more complete visualization of the pelvic organs (Figures 37.10 and 37.11) [53]. In the pediatric population, retrograde cystography and VCUG have been used to diagnose vesicoureteral reflux [54]. When a urethral diverticulum is suspected, positive-pressure urethrography has been shown to be more sensitive than VCUG [55–57], but x-ray imaging has been largely replaced by US imaging and particularly MRI that is now considered the gold standard for proper delineation of the diverticulum anatomy and the relation with the surrounding structures [58–60].

Quantification of Bladder Neck Mobility

VCUG was pioneered by Mikulicz-Radecki in 1931 [61]. The technique was further developed by Stevens and Smith with the introduction of a metallic bead to identify the urethra and by Ardran et al. who proposed the use of cinematographic technique with the opacification of the vagina and rectum [62,63]. The combined use of imaging and pressure–flow recordings was proposed in the 1960s and 1970s and rapidly gained acceptance in the urological community [64,65]. The description of VCUG methodology goes beyond the scope of this chapter but the interested reader can find details about the technique’s history and methodology in a review by Olesen [57]. A number of different parameters of VCUG have been proposed and assessed for reliability over the years. The posterior urethrovesical (PUV) angle is defined by two lines passing along the posterior urethra and the trigone [8]; cutoff values of 115° or more were proposed [3,9]. The degree of urethral inclination is calculated as an angle between the proximal urethral axis and the vertical plane; unfortunately, the angle also varies with pelvic inclination, although cutoff values of <45° or >45° have been described [3]. The angle between a line through the middle of the internal urethral orifice and the urethral knee and a line through the posterior surface of the symphysis and the lowermost part of the obturator foramen closest to the film is defined as the urethropelvic angle (values of 95° are measured in controls and a cutoff value of 70° has been proposed to diagnose bladder descent) [61]. The symphysis orifice (SO) distance is measured at rest as the distance on a horizontal line from the symphysis to the internal urethral orifice (normal values are 31 mm and values <20 mm are the cutoff points for descent and were used to diagnose anterior bladder suspension defects or bladder base insufficiency) [61,66]. In continent women, the urethral axis at rest (UAR) was found to be related to age ($R^2 = 0.28$); patients with UI had a mean UAR of 25° and a mean urethral angle at straining (UAS) of 43°. Showalter et al. measured UAR and UAS before and after surgery showing that both angles returned to near normal after surgery suggesting a correlation between the correction of the defective bladder support and cure [67]. The funneling of the proximal urethra, the flatness of the bladder base, and the most dependent portion of the bladder base are important qualitative parameters estimated on straining films [9].

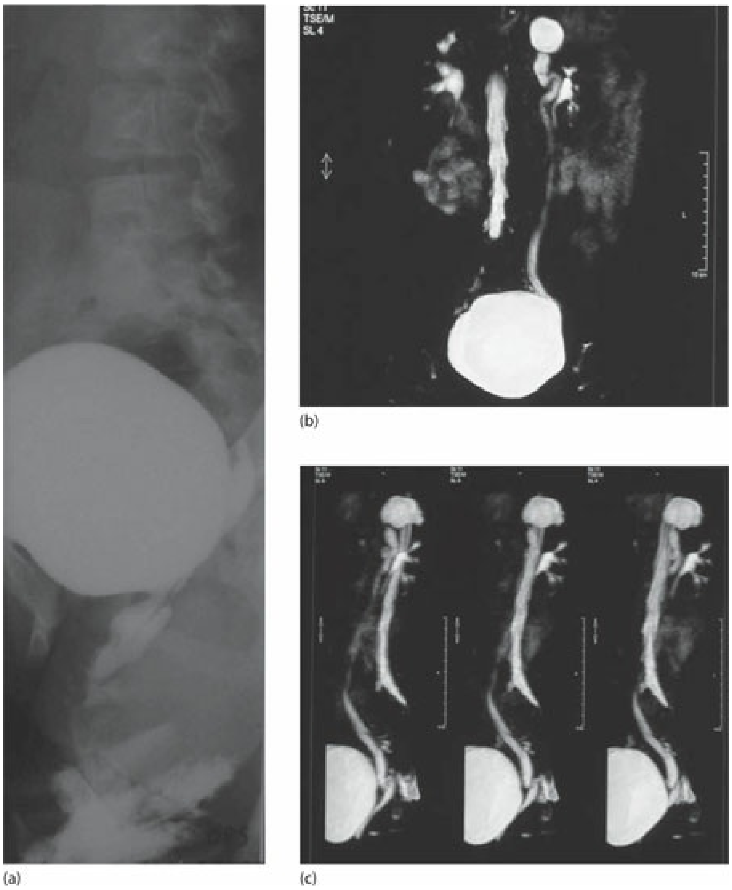

Figure 37.2 Intravenous pyelography in a 16-year-old patient with urinary incontinence. The intravenous pyelogram shows a complete duplex system on the left side. On a lateral projection, the ureter of the upper renal moiety travels below the bladder base, reaching the most distal part of the urethra (a); the anatomic condition is confirmed on uro-MR (b and c). (Courtesy of Prof. G. Tomiselli.)

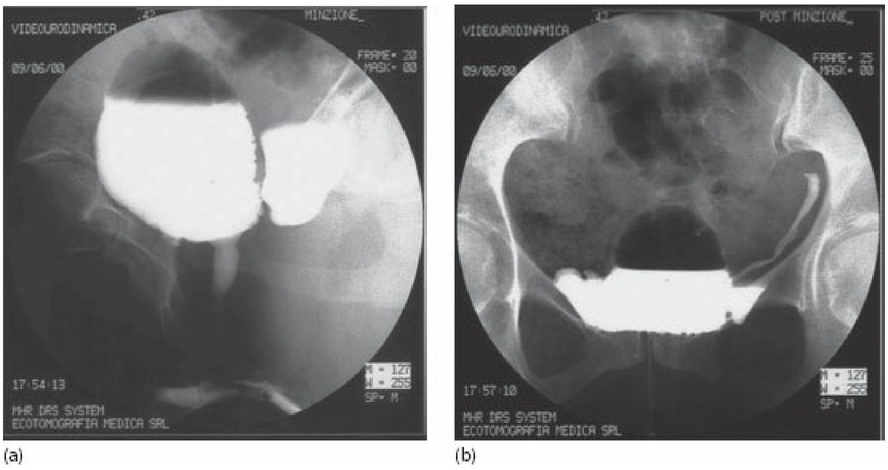

Figure 37.3 Digital fluoroscopy picture obtained during videourodynamics in a 63-year-old female with voiding dysfunction. The dilation of the proximal urethra and a bladder diverticulum is evident on a voiding picture (a); vesicoureteral reflux is apparent on the postvoiding image (b). (Courtesy of Prof. G. Tomiselli and Prof. A. Carbone.)

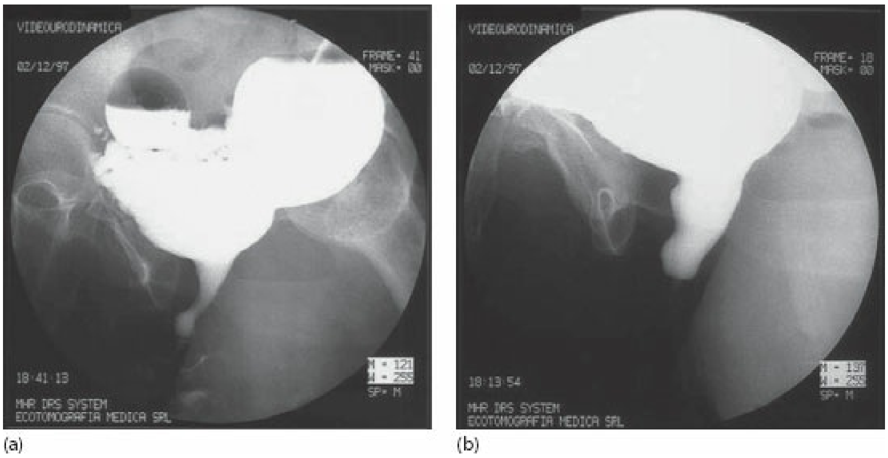

(a) (b)

The analysis of the peer-reviewed literature suggests VCUG is not discriminant between continence and incontinence although promising data have been also published [3,5,10,67,68]. Interobserver and intraobserver agreement values of 43%–79% and 53%–99%, respectively, have been reported for VCUG parameters [9,69–71]. Overall, specificity and sensitivity values of 44%–76% and 53%–100%, respectively, were published [10,72]. The type and degree of suspension defects were not related to the degree of SUI [6,69,70], with positive and negative predictive values of 0.70 and 0.52, respectively, on voiding colpocystourethrography [4,66]. Comparison of VCUG and US imaging suggested a good degree of correlation between the two techniques, particularly with regard to bladder neck position and mobility, PUV, urethral inclination, SO distance, and rotation angle [6,72–74]. Similar values of specificity, sensitivity, and interobserver agreement were also found. The availability and user-friendliness of the US technique favor its use in most urogynecology practices. VCUG was also compared to MRI and comparable data for bladder neck position and cystocele descent were found [75,76]. Although the difference in the patient position between VCUG (standing) and MRI (lying) is of concern, comparison of standing and lying colpocystourethrography did not show any significant difference [76].

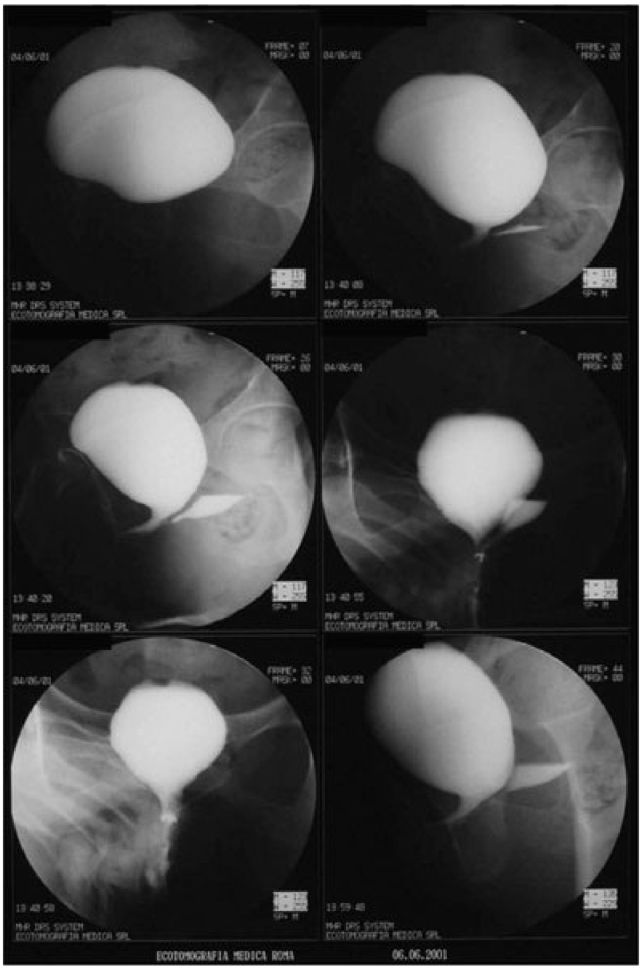

Figure 37.5 Voiding cystourethrogram in a 29-year-old patient with urinary incontinence. During the voiding phase, reflux of contrast medium into an ectopic ureter draining the upper moiety of a complete duplicated left renal system can be seen. In the last phase of the voiding study, the refluxing medium drains into the urethra. (Courtesy of Prof. G. Tomiselli.)

Overall, VCUG studies of women with and without UI failed to provide evidence of clinical utility. Several published studies showed significant overlap in the degree of bladder neck mobility and restoration of normal bladder neck mobility following surgery was not necessarily associated with the cure of UI. These data, together with the introduction of US imaging and MRI of the pelvic floor, obviated the need for VCUG in the management of the standard patient with UI or POP. Although both US imaging and MRI opened a series of new perspective in the imaging of patients with UI, the measurement of bladder neck mobility failed to be of any clinical utility whatever technique was used.

Videourodynamics

The technique is sometimes considered the "gold standard" in the evaluation of LUTD [69]. Actually, there is no evidence that the combination of retrograde and voiding cystourethrography plus cystometry is superior to the two examinations performed separately; however, videourodynamics (VUDN) is frequently performed for convenience in the neurogenic population with LUTD [77–80] and in the pediatric population when indicated (e.g., suspicion of vesicoureteral reflux) [81,82]. The use of VUDN in female patients with UI is not recommended although it may play a role in selected cases. One study compared VCUG with VUDN in women with LUTD and found that in 7.5% out of 200 patients, a correct diagnosis could only be made on VUDN [69]. Although these data are certainly appealing, the small x-ray hazard should also be considered [53,63,83–85].

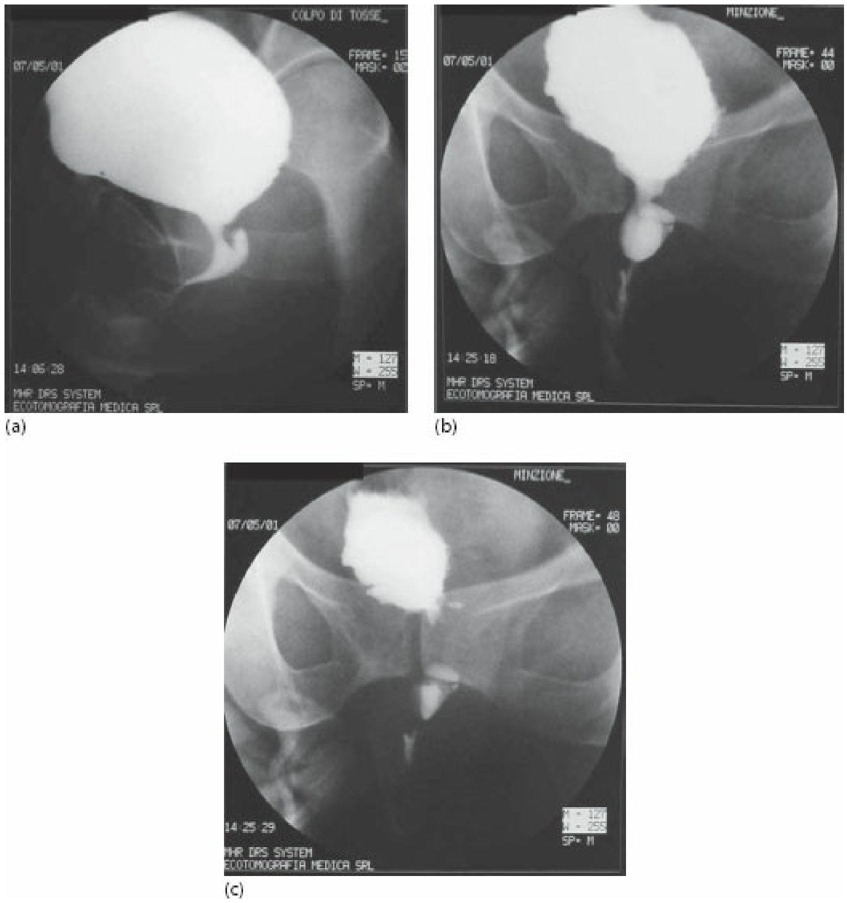

Figure 37.6 Urethral diverticulum of the posterior urethral wall is evident on voiding cystourethrogram in oblique (a) and in anteroposterior projections (b, c). (Courtesy of Prof. G. Tomiselli.)

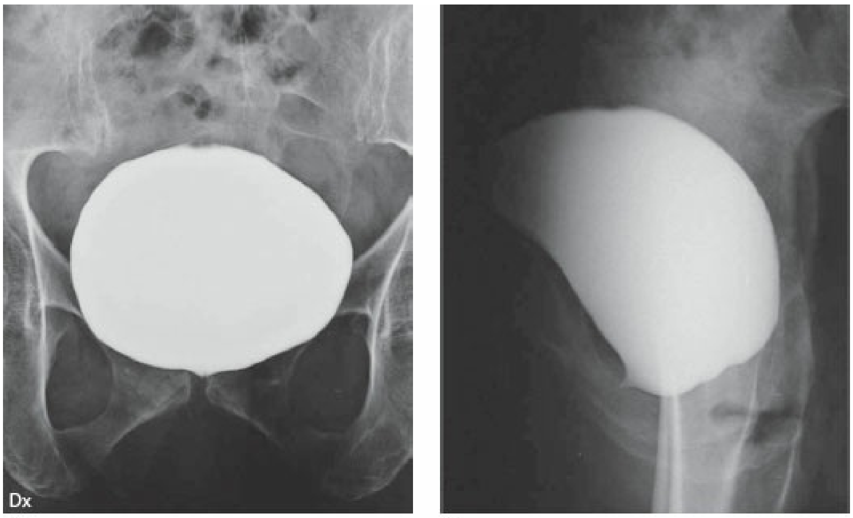

Figure 37.7 Cystourethrography in a 68-year-old patient without urinary incontinence. A symmetrically distended bladder is evident on the anteroposterior image (a), with the bladder base above the lower margin of the symphysis pubis; in the true lateral projection (b), the anterior and posterior urethrovesical angles are easily observed in the picture taken just before micturition. (Courtesy of Prof. G. Tomiselli.)

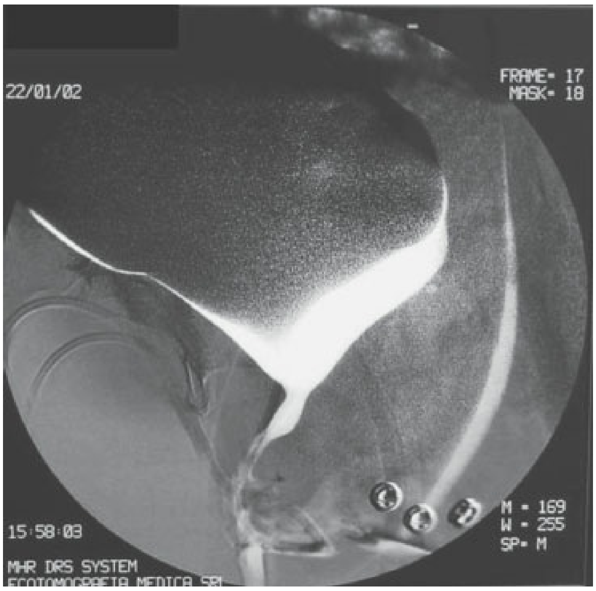

Figure 37.8 Voiding cystourethrogram with digital subtraction. There is normal funneling of the bladder neck with mild downward displacement during micturition. (Courtesy of Prof. G. Tomiselli and Prof. A. Carbone.)

CONCLUSIONS

The use of x-ray imaging in female patients with UI and POP is limited. IVU, CT, and MRI of the UUT maintain a diagnostic role when evaluation of the renal moiety is needed in patients with ectopic ureters and the condition of the UUT needs to be monitored. X-ray imaging of the LUT is not recommended in the standard female patients with UI or POP. Notwithstanding a large body of evidence is available in the peer-reviewed literature concerning diagnostic accuracy, intra- and interobserver variability, and comparison with other imaging techniques, VCUG cannot be recommended in the evaluation of the standard patient with UI or POP. VCUG is not recommended for the diagnosis or classification of UI. The technique may still have a role in the evaluation of complex patients and in patients with recurrent UI or POP.

ULTRASOUND OF THE LOWER URINARY TRACT IN URINARY INCONTINENCE

In clinical practice, imaging of the female urethra is usually performed whenever the presence of a diverticulum is suspected.

Although diverticula can easily be shown on US, better anatomical definition is achieved with MRI that is thus considered the “gold standard” technique. Proper knowledge of the imaging characteristics of the normal female urethra is of importance for adequate interpretation of findings. Transurethral, perineal, transvaginal, and transrectal imaging can be used. The echogenic characteristics of fibrous and muscular structures depend on the angle between the exploring beam and orientation of the muscle fibers. When the normal female urethra is imaged from a perineal approach, the US beam is parallel to the structures and the internal sphincter appears hypoechogenic; when the US beam is orthogonal to the structures such as in transvaginal/transrectal imaging, smooth muscle fibers appear hyperechogenic. Thus, it is difficult to evaluate possible changes to urethral tissues (e.g., fibrosis) on US since the echogenic pattern of it also depends on how the imaging is performed. Furthermore, the echogenic pattern of the female urethra may change during dynamic imaging because of the rotation of the structure on Valsalva and the relative change of incidence between the US beam and the internal sphincter.

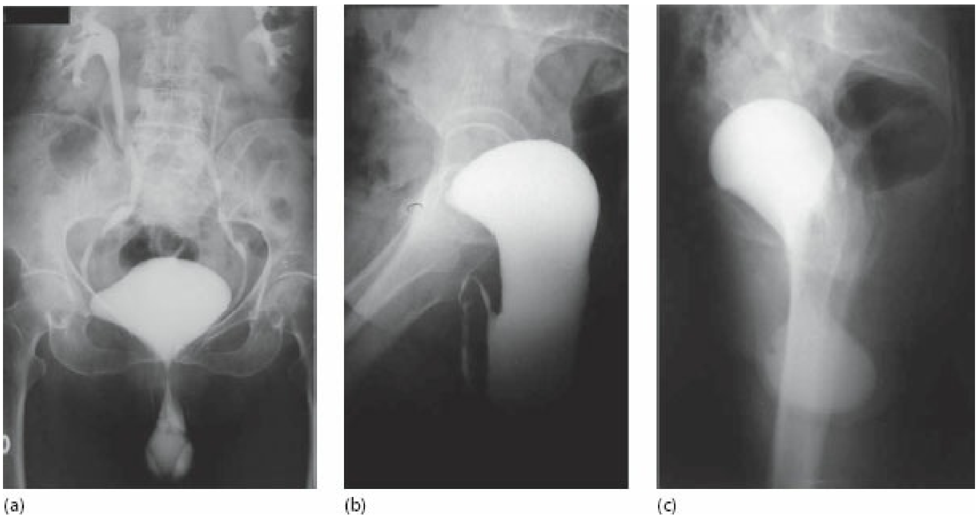

Figure 37.9 Grade IV genital prolapse can be observed in a 63-year-old patient during intravenous pyelography in anteroposterior (a) and true lateral projection (b); the relationship between pubic bone, bladder trigone, and urethra is best appreciated during voiding cystourethrogram in a true lateral projection (c). (Courtesy of Prof. G. Tomiselli.)

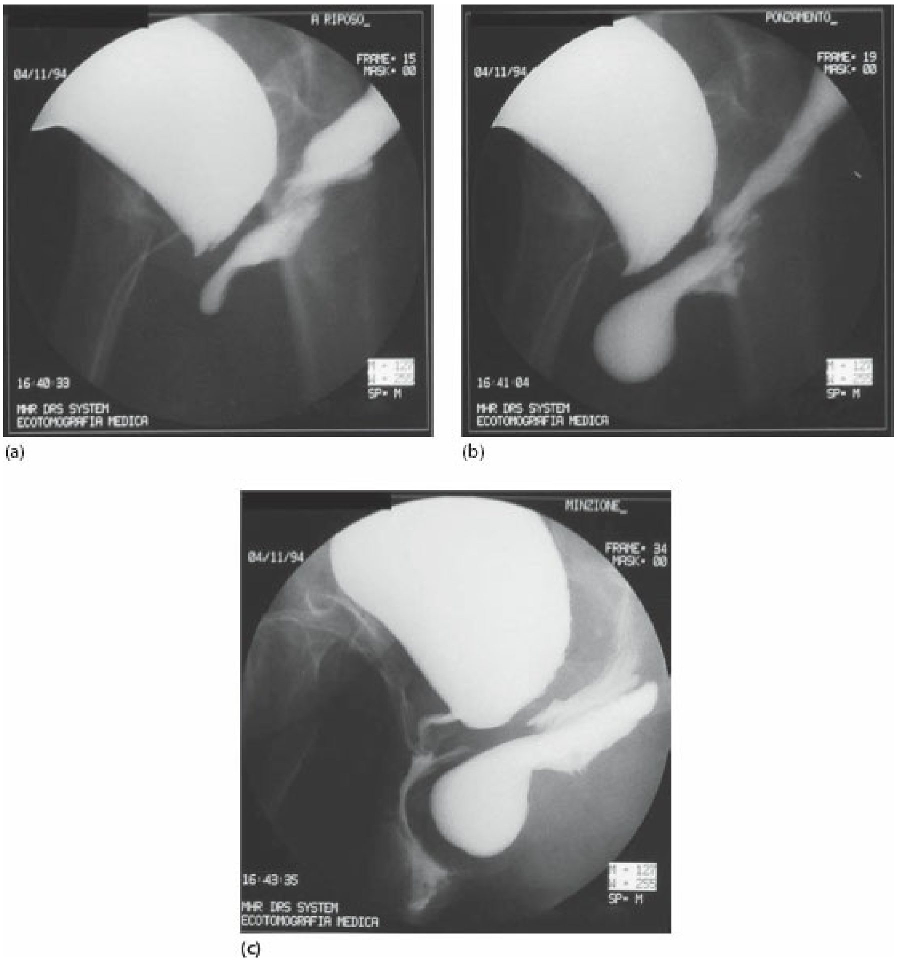

Figure 37.10 Voiding cystourethrogram in a patient with contrast medium both in the bladder and in the rectum. Pictures taken at rest (a), during Valsalva (b), and during voiding (c) show a gradual distension of the rectocele pouch. (Courtesy of Prof. G. Tomiselli and Prof. A. Carbone.)

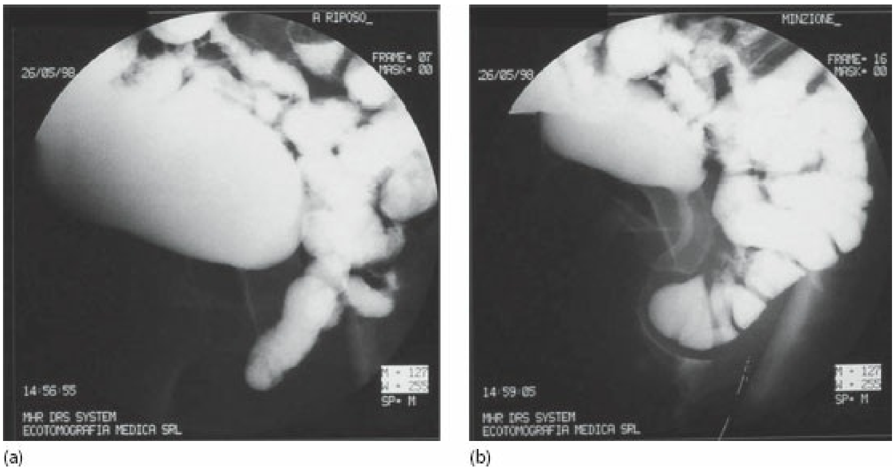

Figure 37.11 Cystourethrography with simultaneous administration of small bowel contrast allows the diagnosis of enterocele in a 61-year-old patient suffering from vaginal vault prolapse. Small bowel protruding down to the perineum level can be observed both at rest (a) and during voiding cystourethrogram (b), with a significant increase of the enterocele mass when abdominal pressure increases. The external sphincter is known to be hyperechogenic on US (Figure 37.12) and is more difficult to visualize. The rationale of assessment of the thickness and volume of the female urethra in SUI relies on the hypothesis that these measurements and the strength are related, so that measurement of sphincter volume could be a proxy for the parameters of the urethral pressure profile (UPP). The measurement of the urethral sphincter has been shown to be reproducible [86–88]. Urethral volumes as assessed with a formula using 2-D measurements and 3-D volume measurements differed significantly [88]. The measurement of the striated sphincter volume seemed to be of importance as this was found to be related to symptoms and signs of SUI [86,87] and with UPP [89–92]. Urethral sphincter volume was associated with the outcome of surgery for SUI [93].

Right or wrong, pelvic floor imaging in SUI patients aims mainly at the quantification of bladder neck mobility. The bladder outlet is easily visible on US, independently from the degree of filling. The position of bladder neck with respect to the lower margin of the pubic bones is measured at rest and during provocative maneuvers (coughing, Valsalva maneuver), thus reproducing the conditions under which SUI occurs in a particular patient. Bladder neck displacement can also be measured during squeezing [94]. During Valsalva, the bladder neck and urethra are considered to rotate posteriorly and inferiorly (caudally and dorsally), and the displacement can be measured in different ways [95–99] with reasonable clinical reproducibility [100,101]. The large variability of urethral mobility in continent nulliparous women (1–40 mm) [102–105] makes the provision of normative data impossible. Parous women are known to have a larger degree of bladder neck mobility than nulliparous [92,94,106–109] and hypermobility is considered to be associated with SUI [24,106]. The sensitivity and specificity of US imaging of bladder neck mobility for the diagnosis of SUI vary between 92% and 96% [109] and 83% and 68% [110], respectively. Analysis of urethrovesical movement patterns on dynamic perineal US imaging in continent and incontinent women did not result in any characteristic movement pattern being associated with SUI [111]. Notwithstanding a huge research effort, US imaging of the bladder neck failed to provide a significant advantage in the management of patients with SUI [112,113]. The comparison of interobserver variability of different methods to quantify urethral mobility, such as Q-tip test, Sensor-Q^{TM} test, and US, showed a lower interobserver reliability for the US imaging technique [114].

POSTVOID RESIDUAL URINE

Measuring postvoid residual (PVR) in patients with UI and POP is considered part of the safety assessment before and after surgery. PVR is not uncommon in women with LUTD and is considered to be associated with an increased risk of urinary tract infection. The condition may develop de novo following surgery for SUI and POP. Since US imaging was first used in the evaluation of PVR, it has been regarded as the gold standard compared to catheterization [115–118]. To correct for deviations of the bladder shape from a sphere, various formulae have been proposed with different correction factors. In a study comparing 12 formulae, the formula “π × height × width × depth in centimeters/6” showed the best agreement between US volume and catheterized volume [119]. In daily clinical practice, the residual volume is probably best approximated by height × width × depth in centimeters × 0.5. Automated US systems are widely used as they have been shown to be accurate and usable by nursing staff [120]. Data from asymptomatic peri- and postmenopausal women suggest a median PVR of 19 mL with 95% of subjects having a PVR < 100 mL [116]. In another study, women with LUT symptoms showed an average PVR < 30 mL in 81% of cases; larger volumes were associated with increasing age, higher grades of POP, and increased prevalence of recurrent urinary tract infections [121].

BLADDER WALL THICKNESS MEASUREMENT FOR THE DIAGNOSIS OF DETRUSOR OVERACTIVITY

In 1994, Khullar et al. showed a significant difference in the bladder wall thickness (BWT) of female patients with detrusor overactivity (DO) and controls (6.7 ± 0.6 mm vs. 3.5 ± 0.6 mm, respectively). In 1996, US evaluation of BWT was proposed as a diagnostic tool to identify patients with DO, since 94% of women with a urodynamic diagnosis of DO had a BWT > 5 mm. Confirmatory data were published in 2002 and 2003. The lack of standardization in the US measurement of BWT hampered a more widespread adoption in daily practice. Promising results on automated measurement of BWT were published and confirmatory data are eagerly awaited [122,123]. Although several papers confirmed the diagnostic value of BWT measurement for the diagnosis of DO, a retrospective analysis of a patient cohort undergoing perineal US for pelvic floor evaluation showed only a low diagnostic accuracy of BWT measurement [124]. Automated systems for the measurement of BWT and US estimated bladder weight did not provided yet the expected improvement in the measurement accuracy and standardization of the technique.

IMAGING OF PELVIC FLOOR MUSCLES

Different groups have investigated pelvic floor anatomy [204] and biomechanics [125–130,205] and much progress has been made in recent years. Computer models have shown that the pelvic floor muscles need to stretch 3.3 times their normal muscle length [130]. Avulsion traumas of the levator ani muscle (LAM) from the pubic bone have been shown to be associated with POP in the anterior and central compartment [131,132], even if not every LAM defect described on US correlates with increased hiatal distention or bladder neck descent [206,207,210]. Recently, the moment of inertia of the pelvic floor muscle (PFM) has been evaluated as a new parameter of pelvic floor damage involved in the pathogenesis of POP [209]. From a clinical standpoint, however, research on imaging still needs to provide an answer to the hypothesis that information on pelvic muscles morphology can predict the outcome of physical and surgical intervention for UI and POP. US and MRI seem interchangeable when evaluating pelvic floor anatomy at rest [211].

The evaluation of pelvic floor function may be considered as an integral part of the physical examination in patients with UI or POP, and US is increasingly used for this purpose. US imaging of pelvic floor muscles during exercise has been used as a strong biofeedback for the patients undergoing pelvic floor rehabilitation [133,134]. The importance of good pelvic floor function is proven by the significant therapeutic effect of pelvic floor rehabilitation in UI. Significant changes in imaging parameters were found following exercise, including bladder neck resting position [135], PFM thickness [136], and levator hiatus area [212,213]. Parameters like the cranial lift of the urethra in relation to the pubic bones during squeezing, the dimension of the genital hiatus, and the posterior anorectal angle were measured on US, but the sensitivity of US parameters may not be enough to assess the state of PFM function, and even correlation with data obtained from palpation and perineometry is still under debate [27,137–140,214].

Measurements of pelvic muscle thickness and volume may be performed with 3-D US (Figure 37.13) and MRI [22,141–144], but only low test–retest and interobserver variability have been observed [22,145,146]. Normative data in healthy controls and athletes have been published [102,136,147]. As one could expect, pelvic floor muscles were found to be thinner in women with POP [24,148–150] or UI [148,151] and their genital hiatus was larger [152]. Women who undergo regular exercise had thicker muscles compared to controls [147] and Chinese women had thinner muscles than Caucasians [144]. Pelvic floor function depends on the integrity of its different muscles (Figure 37.14). The levator ani, or in more detail the sling of the puborectal muscle, may suffer avulsion from the pubic bones in vaginally parous women who have delivered vaginally [215], and the risk of trauma increases with maternal age at first delivery [153]. Levator trauma has been observed at the time of labor but no effective therapeutic measures have been identified [154,155]. Muscle detachment is best visualized when the muscle contracts as this maneuver increases the gap with the pubic bone. On an axial plane, the loss of the characteristic H shape of the vagina is an indirect sign of levator ani detachment [112,156], and it is considered to correspond to what was previously described as paravaginal defects [157–160]. Methods for quantification of muscle defects on MRI [161] and US imaging [143] have been proposed; levator–urethra gap, levator–symphysis gap, and puborectalis attachment width may be diagnosed reliably by both techniques [216]. MRI is attractive and promising but still may fail in detecting LAM defects [217]; thus, new techniques have been explored and diffusion tensor imaging with fiber tractography seems to allow a good 3-D visualization of pelvic floor [218].

Levator ani detachment (Figure 37.15) observed on US and MRI is associated with a two- to sixfold increase in the risk of POP irrespective of hiatal area enlargement [154,216,219–222] in the anterior and central compartments [131,162] and of fecal incontinence (FI) [220,223,224]. Avulsion of the muscle did not seem to be associated with an increased risk of SUI [163], and overall, LUTS are less frequent in women with POP and major LAM injuries rather than in women with minor LAM defects [225]. Muscle detachment from the pubic bone is associated with decreased muscle strength on physical examination [157], with a more caudal position of perineal structures and larger hiatus at rest or during physical exercise, irrespective of POP [226,227]. LAM defects as described on MRI correlate well with outcome of POP surgery, the major defects being associated with worse vaginal support after surgery. The correlation between detection of avulsion on 3-D US imaging and palpation is poor [164] mainly due to high interobserver variability in the physical examination of muscle defects unless adequate training and expertise are available [165,228,258]. The measurement of the genital hiatus on US (Figure 37.16) is a reproducible measurement [22,156,220], and data at rest correlate well with MRI data, although a lower degree of correlation was found during Valsalva [142,145]. Values of >30, >35, and >40 cm^2 were described as mild, moderate, and severe ballooning of the genital hiatus [166]. In nulliparous women, areas of 6–36 cm^2 have been measured [147,152]. Vaginal delivery was associated with an enlargement of the levator hiatus [167,230,231]. Hiatal dimensions at rest, at contraction, and in some cases at Valsalva were further correlated with the severity of POP [129,143,149,208,229]. A recent study has shown that virtual reality measurements of the levator ani hiatus volume are comparable to those obtained with conventional 3-D ultrasonography [232]. On MRI of the dimensions of the bony pelvis at the level of the muscular pelvic support, no differences in these dimensions could be found between women with and without POP [161,233].

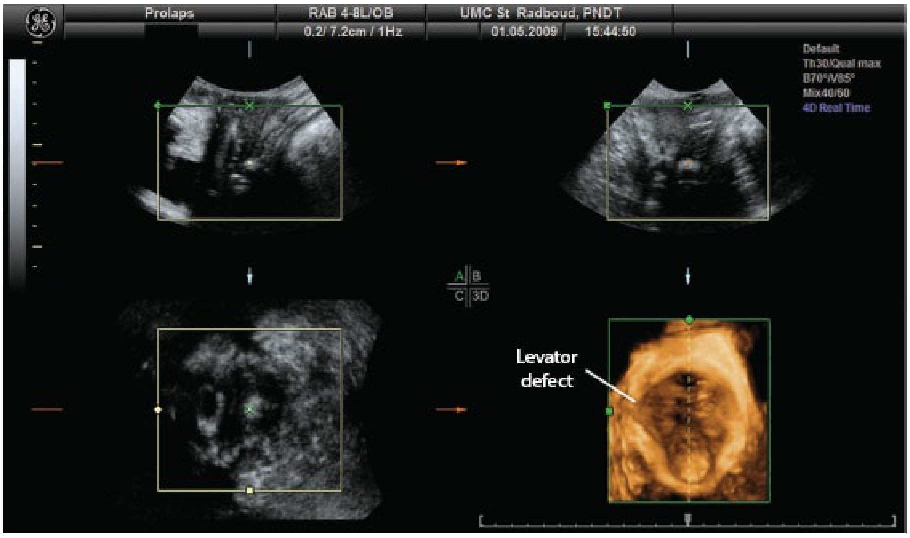

Figure 37.13 Perineal midsagittal (left upper), coronal (right upper), and axial (left lower) two-dimensional view and three-dimensional rendered image (right lower). The rendered image suggests a right-sided levator defect, which needs to be confirmed in the tomographic ultrasound imaging.

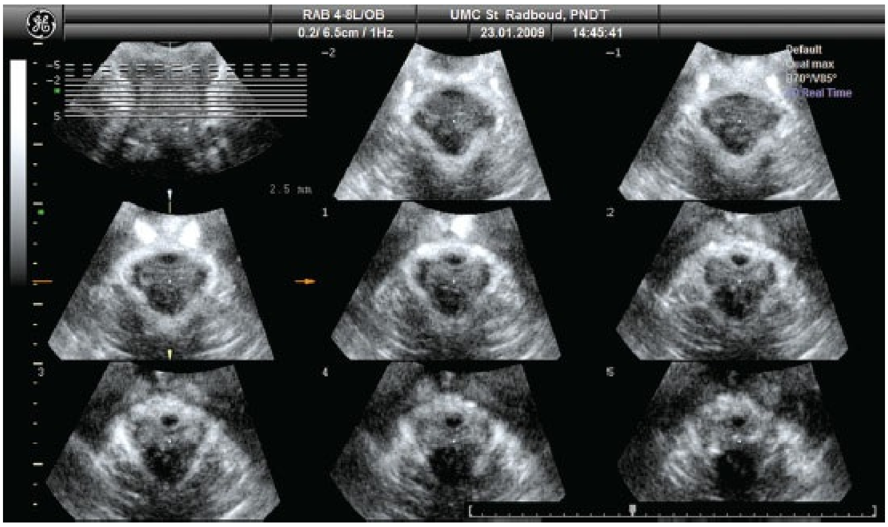

Figure 37.14 Tomographic ultrasound imaging in oblique axial plane. Normal attachments of the levator ani muscle.

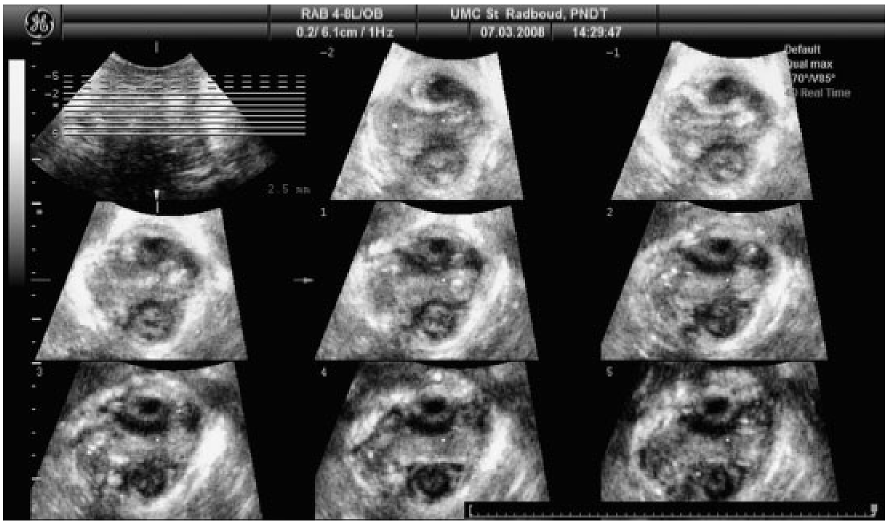

Figure 37.15 Tomographic ultrasound imaging in oblique axial plane. Right-sided avulsion of the levator ani muscle from the symphysis pubis (levator defect).

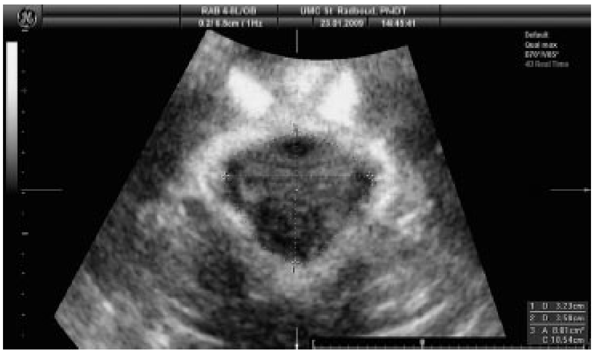

Figure 37.16 Perineal two-dimensional image in oblique axial plane. Measurement of hiatal dimensions.

US imaging and MRI are both appropriate methods in the investigation of the integrity of sphincter ani muscle. On US, the internal anal sphincter can easily be visualized, whereas for the external sphincter, more expertise may be needed [168]. A recent study has shown that thickening of the internal sphincter occurred with increasing age, whereas only thinning of the external sphincter correlated with fecal incontinence but not with aging [169]. Together with EAS injuries during delivery, levator ani major defects seem to contribute to the development of FI [223].

IMAGING OF PELVIC ORGAN PROLAPSE

There is a large natural variability in the degree of pelvic organ descent for all three compartments in nulliparous and parous women, with at least 15% of nulliparas showing functional abnormality of the LAM [234]. After delivery, an increase of pelvic organ mobility was found in all compartments [170]. A correlation was also found between increase of organ mobility, length of the second stage of labor, and mode of delivery. Operative vaginal delivery was associated with the highest rate of increase in pelvic organ mobility. Generally speaking, the effect of vaginal delivery on pelvic organ descent is more evident in the anterior and central compartment than in the posterior one [171,172]. The first delivery has a larger impact on bladder neck descent than the subsequent ones [89]. Interestingly, pelvic organ mobility is not merely a negative factor as US imaging performed during pregnancy showed that a larger bladder neck mobility and a larger and more distensible genital hiatus were associated with normal vaginal delivery [172,173]. On the other hand, women with anterior POP have a 67% more compliant support system compared to women without POP, and levator ani deficiency severity is associated with grade of POP [235,236]. Unfortunately, greater bladder neck descent is also associated with a higher risk of UI [28].

The sensation or visualization of a bulge in the vagina has shown to be the only symptom that correlated with the degree of POP [174,208]. This finding was irrespective of the method used for the quantification of the degree of POP: POP quantification (POP-Q), dynamic MRI, or US imaging [175,237]. There is one study where POPQ predicted prolapse symptoms better than US [176] and another where levator hiatal area as measured by 3-D US is strongly associated with signs and symptoms of POP [131]. A cutoff of more than 6 cm for genital hiatus (gh) plus perineal body (pb) that is equivalent to hiatal area on US seems to show optimal sensitivity and specificity in predicting objective and subjective prolapse, as well as prolapse recurrence after surgery when gh + pb is equal or more than 8.5 cm [149,238–240]. Moreover, recent findings recommend sustained Valsalva maneuver for at least 6 seconds or two to three times to best assess hiatal distention and POP by transperineal US, and this might further ameliorate imaging techniques specificity, if properly performed [241,242,259,260]. In MRI, various reference lines for quantification of POP have been studied, and the pubococcygeal line had shown minor superiority [25,177]; thus, for the sake of standardization, the use of this line has been advocated, but more recently, the MPL has been employed with success [243,244], and the LASV, the volume bounded inferolaterally by the levator ani muscle, has shown good correlation with clinical findings [245]. Of note, MRI allows the dynamic study of the pelvic floor with at least two different pulse sequences—true FISP and HASTE—which may contribute to a better patient assessment than other techniques [246]. In US, the lack of a reference line through two bony points is an obvious limitation. A horizontal line passing through the lower margin of the symphysis pubis has been used [178], whereas a line through the anal canal is used as a reference point to quantify the severity of rectocele (Figure 37.17) [178]. A cutoff value of 15 mm for descent below the line through the symphysis and of 20 mm for the depth of a rectocele has been proposed as a threshold for symptomatic prolapse [179]. Good reproducibility and correlation have been shown for the anterior compartment as assessed on MRI and US imaging [20,178,180] and physical examination. The assessments may thus be interchangeable and the additional value of imaging techniques seems limited in this compartment, as well as in the central one [20, p. 176,247]. Imaging of the posterior compartment has also been explored in several studies [179,181,184]. Poor, moderate, and good interobserver variability in US imaging and MRI has been described [100,177,182,185]. Comparison of x-ray imaging and US showed similar rates of detection for enteroceles (71%) [184]. Although US and clinical staging or intraoperative findings correlated well [24,181,183], one-third of patients with clinical enterocele (Figure 37.18) were negative on US. Furthermore, no clinical benefit has been identified from US imaging of enteroceles, while MRI seems more accurate [247]. The posterior anorectal angle can be measured on US with a good degree of correlation with defecography [179,184,186]. The clinical meaning of perineal descent and the best assessment method has not been fully unraveled. MRI is able to identify high rates of posterior prolapse, especially when the MPL line is employed, even those without clinical significance [20,244,248,249]. In four studies, which have assessed the correlation between POP symptoms and perineal descent on US imaging, MRI, and defecography, a statistically significant correlation was observed in all studies [174,175,184,187,250]. Although imaging of POP is captivating, the question whether imaging is superior to clinical examination remains open.
